## GERMAN MEASLES

(RUBELLA)

**Definition.** German measles is a common communicable disease of childhood characterized by mild constitutional symptoms, a rash similar to that of mild measles or mild scarlet fever, or a combination of them, and enlargement and tenderness of the postoccipital, retroauricular and posterior cervical lymph nodes.

**History.** Wagner in 1829 distinguished German measles from measles and scarlet fever. The need for recognition has been re-emphasized by the work of Gregg in 1941, who observed severe congenital anomalies in newborn infants whose mothers had German measles during early pregnancy.

**Etiology.** German measles is caused by a viral agent, which Hiro and Tasaka in 1938 transferred successfully to children with nasopharyngeal secretions filtered through Seitz EK and Berkefeld W filters. It has also been grown on the chorio-allantois of the developing chick embryo by Habel. Anderson in 1949 demonstrated the presence of rubella virus in throat washings at the time of onset of the rash and the occurrence of German measles without rash (inapparent infection). Krugman and co-workers (1953) showed

that rubella virus could be obtained from the blood two days before and on the first day of the rash.

**Epidemiology.** Transplacental immunity is well recognized and is lost by about six months of age. Epidemics occur approximately every three to four years, but are not as extensive as those of measles. A single attack apparently produces permanent immunity, and second attacks almost never occur. The higher incidence of German measles among adults, in contrast to that of chickenpox and measles, suggests that German measles is less contagious than either of these diseases.

**Clinical Manifestations.** The incubation period for German measles is generally fourteen to twenty-one days, but may be slightly shorter or longer. The prodromal phase of mild catarrhal symptoms is shorter than that of measles and may be so mild as to go entirely unnoticed. The most characteristic sign, of which the patient frequently complains, is the presence of retroauricular, posterior cervical and postoccipital adenitis. No other disease causes the tender enlargement of all these nodes to the same extent that German measles does. An enanthem often appears just prior to the onset of the skin rash. It consists of discrete rose spots on the soft palate which may coalesce into a red bluish and may extend over the fauces.

The rash does not appear until the nodes have been enlarged for approximately twenty-four hours. The rash is much more variable than that of measles. It starts on the face, but its evolution is so rapid that it may be fading on the face by the time it appears on the trunk. Maculopapules are usually present in large numbers and are discrete, but in addition to the eruption there are large areas of flushing which spread rapidly over the entire body within twenty-four hours. The rash may be confluent, particularly on the face. In many instances, during the second day, the rash will change to a more pinpoint appearance, especially over the trunk, resembling that of scarlet fever. By the third day of the disease the rash usually disappears; owing to the lack of hemorrhages into the lesions, any residual brown pigmentation lasts only a few days, and there is only slight desquamation.

The pharyngeal mucosa is reddened, and the conjunctivas are slightly inflamed. Photophobia is not present as in measles. There is slight or no fever accompanying the rash, but, when present, it is always when

the rash is full blown and persists for one, two or occasionally three days. The temperature rarely exceeds 101° F. Anorexia, headache and malaise are not frequent. The spleen is often slightly enlarged. Mild itching is sometimes present. There are no characteristic changes in the white blood cells; the total cell count remains normal or is slightly reduced.

**Differential Diagnosis.** Particularly in its more severe forms, German measles may be readily confused with the mild types of scarlet fever (p. 408) and measles (p. 485). *Exanthem subitum* is readily distinguished from German measles by the appearance of the rash at the end of the febrile episode rather than at the height of the signs and symptoms. *Drug rashes* are at times extremely difficult to differentiate from German measles. The characteristic enlargement of the lymph nodes would, of course, point to German measles. *Infectious mononucleosis* at times has a rash similar to that of German measles and is easily confused with it because of the enlargement of the lymph nodes. The alteration in the blood picture, however, should be sufficient to differentiate the two diseases.

**Prognosis and Complications.** Under ordinary circumstances there are few complications, and the signs and symptoms subside as rapidly as they appear. Neuritis and arthritis occasionally occur. Resistance to secondary bacterial invaders does not seem to be lowered. Encephalitis similar to that in measles is a relatively important complication, and a number of deaths have been recorded.

Microcephaly, deafness with secondary mutism, cardiac anomalies and congenital cataracts are found relatively frequently in infants whose mothers had German measles during the first three months of pregnancy.

**Prevention.** Prophylactic measures are rarely indicated. It is important for girls to be exposed and to contract the disease before the age of child-bearing. Pregnant women should be guarded from exposure to German measles. Apparently immunity in the pregnant mother resulting from a previous attack may not protect her fetus from the serious anomalies secondary to her exposure in the first trimester. Thus, even though the mother has had German measles, she should avoid exposure during the first three or four months of pregnancy.

When isolation is desirable, the exposed susceptible should be kept strictly isolated

from approximately the tenth to the twenty-first day after exposure. Intramuscular injection of gamma globulin or small amounts of pooled adult serum or plasma within the first seven or eight days after exposure may or may not afford protection from, or attenuation of, the disease, apparently depending upon the batch used, upon possible strain differences in the virus or upon other factors as yet unknown. Such prophylaxis is rarely indicated except in early pregnancy. Owing to the lack of danger of viral hepatitis, gamma globulin is the preferable prophylactic agent.

**Treatment.** Unless bacterial complications occur, treatment is symptomatic. The patient should be kept in bed until the temperature is normal. When quarantine appears necessary, it need be continued only two days from the onset of the rash.

## EXANTHEMA SUBITUM

(ROSEOLA INFANTUM)

**Definition.** Exanthema subitum is an acute disease of infants and young children, usually occurring sporadically, but occasionally in epidemics. It is unique in that the diagnostic rash and the end of the disease occur almost simultaneously. The disease is characterized by a period of high fever lasting three to four days, during which time there are insufficient clinical findings to explain the hyperpyrexia, and by an abrupt termination

with a precipitous drop of the temperature to normal and the appearance of a generalized eruption, which fades quickly.

**History.** Zahorsky first described the disease in the United States in 1910 as roseola infantum; later Veeder and Hempelmann applied to it the more suitable term of "exanthema subitum."

**Etiology.** The typical disease has apparently been produced in susceptible infants by injection of blood serum (Kempe and co-workers) and of heparinized blood (Hellström and Vahlquist) from patients with exanthema subitum. A febrile disturbance was similarly produced in monkeys by Kempe.

Nothing is known of the pathologic changes of the disease.

**Epidemiology.** The degree of contagiousness is not known, although it appears to be low. There is a tendency for the disease to occur chiefly in the spring and fall. It attacks both sexes equally. In the rare epidemics described the incubation period was estimated to be from seven to seventeen days. The epidemiologic pattern is not clear. The occurrence of exanthema subitum sporadically in early life with rare epidemics in older age groups suggests the possibility of an endemic spread through most of the population in early infancy and childhood, with production of permanent immunity. Most of the cases occur between the ages of six months and three years, although the disease does occur infrequently in older children and even in adults. The peak of the incidence appears to be during the second year of life.

**Clinical Manifestations.** The onset is sudden, with fever which rises abruptly as high as 103° to 105° F.; convulsions occur on occasion at this time. Although the pharyngeal mucosa is slightly inflamed at times and there may be slight coryza, there are no typical signs. The outstanding feature is the absence of physical findings sufficient to explain the height of the fever. The diagnosis is suspected chiefly by exclusion of other possible infections, particularly those which at this age are the most common causes of high fever and in which the diagnosis may not be evident, such as otitis media, acute pyelonephritis and pneumonia. There is usually a leukopenia, the total cell count being in the range of 3000 to 5000 per cubic millimeter, and a relative lymphocytosis which may be as high as 90 per cent. Occasionally a large number of monocytes are present.

As the fever falls by crisis on the third or fourth day or just before or shortly after its

return to normal, a macular or maculopapular eruption appears which is disseminated over the body, starting on the trunk and spreading to the upper extremities and neck, with slight involvement of the face and legs. The rash quickly fades, rarely remaining as long as twenty-four hours. Desquamation is rare, and no pigmentation remains. In the rare instances of epidemic outbreaks, cases without a rash may be suspected, but a definite diagnosis cannot be made. Clemens described an enanthem on the soft palate consisting of small erythematous spots and streaks. Occasionally the lymph nodes, especially in the cervical area, may be enlarged, but not to the extent that they are in German measles.

**Differential Diagnosis.** The principal difficulty in differential diagnosis is with *German measles*, from which exanthema subitum is distinguished chiefly by the prodromal period of high fever. *Measles* and *dengue* can be distinguished primarily by the time of appearance of their rash in relation to the other clinical findings. In measles, though there is usually a fever of variable degree for three or four days just before the rash, the temperature becomes abruptly elevated to 103° to 104° F. at the time of appearance of the rash and remains elevated for the next two days or so. The lack of Koplik's spots, severe coryza, conjunctivitis and cough also helps to distinguish exanthema subitum from measles. Certain allergic rashes—for example, those resulting from sensitivity to drugs—may be difficult to distinguish from exanthema subitum, but the characteristic clinical pattern of the latter is usually sufficiently definite to establish the diagnosis.

**Prophylaxis and Treatment.** There are no known methods for shortening the course of the disease or for prophylaxis. In infants and young children, who are prone to convulsions, the administration of relatively large doses of a sedative at the appearance of the sharp febrile onset of exanthema subitum may be effective as prophylaxis against such seizures. Aspirin may be of some help in partially reducing the fever and in allaying restlessness.

#### HERPES SIMPLEX

(DISEASES DUE TO HERPESVIRUS HOMINIS)

*Herpesvirus hominis* is a widespread and ancient parasite of man that can produce a number of clinical manifestations. These can be classified under diseases of the skin, the mucous membranes, the eye and the central nervous system and generalized systemic involvement. The lesions at the various sites have the following points in common: (1) Visible manifestations are characterized by vesicle formation; (2) histologic examination reveals an intranuclear inclusion body; and (3) the virus can be isolated with relative ease from infected tissues.

It is now clear that infection may be manifested in two forms: (1) *primary* herpes, in which first exposure of a susceptible host to the virus results in either subclinical infection without symptoms (approximately 85 per cent) or in a general systemic reaction. The latter may be severe and even fatal, associated with a transient viremia and with local lesions in the majority of instances. Circulating antibodies, absent at the onset of the illness, develop during the recovery phase. (2) *Recurrent* herpes, in which the lesion is localized and there is little or no systemic reaction. The recurrent lesions are thought to be the result of activation of latent virus by such nonspecific stimuli as changes in environment, febrile reactions, menstruation and emotional upsets. Such reactions occur only in persons who have had a primary infection and consequently have circulating antibodies at the time of the recurrence.

#### CLINICAL PATTERNS

##### LESIONS OF THE SKIN

(HERPES LABIALIS, FACIALIS, FEBRILIS)

Lesions of the skin are usually a manifestation of the recurrent disease; they begin with a feeling of irritation or burning pain in the area of skin involved, followed by the appearance of a group of closely aggregated reddish

papules which quickly vesiculate. These thin-walled vesicles on an erythematous base rupture, scab and heal in a week or ten days without leaving a scar; temporary depigmentation may occur in the Negro. In children the vesicles often become secondarily infected and then must be distinguished from impetigo contagiosa. The lesions tend to occur at mucocutaneous junctions, but may occur anywhere, and tend to recur at the same site.

#### TRAUMATIC HERPES

This term has been applied to the rare infections of traumatized skin. Scattered vesicular lesions begin to appear in the vicinity of the trauma; the regional lymph nodes become enlarged and tender. The clinical picture may be mistaken for that of herpes zoster since in the extremities the lesions extend centripetally as grouped vesicles. Healing may be delayed for as long as three weeks; recurrences at the site are common. During an attack of herpetic gingivostomatitis, lesions may occur on the digits of "thumb suckers" and also on the face, where they appear as scattered single vesicles in contrast to the grouped vesicles of the recurrent disease. Rarely, primary herpetic infection can occur as an isolated phenomenon on apparently unbroken skin.

#### ECZEMA HERPETICUM

(KAPOSÍ'S VARICELLIFORM ERUPTION,  
JULIUSBERG'S PUSTULOSIS VACCINIFORMIS ACUTA)

(See also p. 1313.) This complication of infantile eczema results from a widespread and usually primary infection of the eczematous skin with the herpes virus. The severity of the complication varies; the attacks may be so mild as to be overlooked without a high index of suspicion and adequate laboratory facilities, or they may be fatal. In a typical severe attack vesicles develop abruptly in large numbers over the area of eczematous skin. They continue to appear in crops for as long as seven to nine days. Isolated at first, they later become grouped and may occur on adjoining areas of normal skin. Wide denudation of the epidermis can occur in areas of confluent vesicles. Scabs eventually form, and epithelization occurs. The systemic reaction varies, but temperatures of 103° to 105° F. for seven to ten days are not uncommon. If eczema herpeticum is a manifestation of recurrent disease, antibodies are present and the systemic involvement is much less severe. Death may occur during primary in-

FIG. 150. Eczema herpeticum. Note similarity of umbilicated vesicular lesions on face to those of eczema vaccinatum (p. 504).

fection as the result of profound physiologic disturbances, associated with loss of fluid, electrolytes and protein or as the result of secondary bacterial invasion. A differential diagnosis from eczema vaccinatum (p. 504) must be made. Apart from specific differentiation in the laboratory, a history of exposure to the appropriate virus and the fact that the herpetic lesions occur in crops will usually distinguish them.

#### LESIONS OF THE MUCOUS MEMBRANES

ACUTE HERPETIC GINGIVOSTOMATITIS  
(ACUTE INFECTIOUS GINGIVOSTOMATITIS, APHTHOUS STOMATITIS, CATARRHAL STOMATITIS, ULCERATIVE STOMATITIS, VINCENT'S STOMATITIS)

(See also p. 633.) This clinical manifestation of primary infection is probably the commonest cause of stomatitis in children between one and three years of age. It can occur in adults. The symptoms may appear abruptly with pain in the mouth, salivation, fetor oris, refusal to eat, and fever, often as high as 104° to 105° F. The onset, however, may be insidious, fever and irritability preceding the oral lesions by a day or two. The

FIG. 151. Herpetic stomatitis.

FIG. 152. Lesions of herpetic stomatitis on the tongue.

initial lesion is a vesicle, seldom seen because of its early rupture. The residual lesion is 2 to 10 mm. in diameter and is covered with a yellow-gray membrane. When this membrane sloughs, a true ulcer remains. Although the tongue and cheeks are most commonly involved, no part of the oral lining is immune.

Submaxillary lymphadenopathy and inflammation of the gums are extremely common and are most important for the differential diagnosis from other forms of stomatitis. The acute phase lasts four to nine days and is self-limited. Pain tends to disappear two to four days before healing of the ulcers is complete. In some instances the tonsillar regions are involved early, and acute tonsillitis of bacterial origin or herpangina (p. 528) may be suspected. In herpes simplex the lesions eventually spread to the tongue and/or the front of the mouth. In herpangina a careful epidemiologic history will usually reveal evidence of other cases in the vicinity.

#### RECURRENT STOMATITIS

Most recurrent stomatitis does not appear to be of herpetic origin; there is evidence that the recurrent, solitary aphthous ulcers previously thought to be herpetic are not caused by this virus. However, some involvement of the mucous membranes inside the lip may be seen with an attack of herpes labialis.

#### HERPES PROGENITALIS

**Female.** Primary herpetic vulvovaginitis may be encountered in childhood and, though uncommon, enters into the differential diagnosis of vulval lesions. The patient complains of burning pain in the genitals. The lesions resemble those in the mouth, appearing as vesicles which soon collapse and form lesions covered with a yellow-gray membrane. These become eroded into superficial, painful ulcers (Fig. 153). There is associated enlargement of the inguinal nodes, and a low grade fever is common. The lesions heal spontaneously; treatment consists of sitz baths for cleanliness.

**Male.** Herpes progenitalis of males is rare in childhood. Primary infection, manifest by a cluster of tiny vesicles surrounding a reddened meatus, has been described in association with stomatitis. In the adult, recurrent herpes appears as clusters of small erosions

FIG. 153. Primary herpetic vulvovaginitis. Note the similarity of the lesions to those of herpetic gingivostomatitis. (From Scott, Coriell, Blank and Burgoon: *J. Pediat.*, Vol. 41.)

(eroded vesicles) on the glans or corona, sometimes associated with typical herpetic vesicles on the shaft.

#### LESIONS OF THE EYE

Conjunctivitis and keratoconjunctivitis may occur as manifestations of either a primary or a recurrent infection. The conjunctiva appears congested and swollen with little, if any, purulent discharge. In the primary infection the preauricular node is enlarged and tender.

The corneal lesions are protean, but dendritic ulcers are almost pathognomonic. The diagnosis may be suspected clinically by a history of recurrence and/or by the appearance of herpetic vesicles on the lids. Proof can be obtained by isolating the virus from the eye and, in a primary attack, demonstrating a rise of antibodies in the serum against the herpes virus. In the differential diagnosis the highly contagious epidemic keratoconjunctivitis (shipyard conjunctivitis) caused by adenovirus type 8 must be considered.

#### DISEASE OF THE CENTRAL NERVOUS SYSTEM HERPETIC MENINGOENCEPHALITIS

The central nervous system is occasionally the site of a primary infection which may take the form of meningoencephalitis, encephalitis or encephalomyelitis (for discussion of clinical manifestations, see p. 547). Encephalitis may be accompanied by other manifestations of herpetic infection.

#### NEONATAL HERPETIC INFECTION

Herpetic infection may occur in the newborn infant, especially the premature. Transmission is from a primary infection in the mother as a rule.

The onset is usually from the fifth to the ninth day of life with fever or hypothermia, lethargy, dyspnea, vomiting, increasing jaundice and, at times, convulsions and circulatory collapse. Vesicular lesions of the skin, mucous membranes or conjunctivitis may or may not be present. Hepatosplenomegaly may occur. Involvement of the esophagus may lead to accumulation of thick yellow mucus in the pharynx, and severe bleeding may accompany liver failure. At autopsy characteristic inclusion bodies can be found in many organs, particularly the liver, where there is evidence of necrosis (herpetic hepatitis). A terminal infection with *Pseudomonas pyocyanea* is common.

#### GENERAL FEATURES OF HERPETIC INFECTIONS

**Etiology.** *Herpesvirus hominis* is a sphere 100 to 150 millimicrons in diameter. Of the common laboratory animals, it can infect rabbits, guinea pigs, hamsters and mice. Suckling mice are particularly susceptible. It grows on the chorio-allantoic membrane of the developing hen's egg, producing characteristic small, oval, superficial pocks. It infects various types of tissue cultured cells, especially rabbit kidney, human amnion and HeLa cells.

**Epidemiology.** Burnet has pointed out that this virus is primarily a parasite of man, which has developed an extremely compatible relationship with its host. About 70 per cent of the population are infected for most of their lives, but the host is rarely disabled and hardly ever killed by this infection. Infants up to four months of age show evidence of passive immunity. Most susceptibles become infected before the age of six years. Clinical manifestations are infrequent until the second year of life, when the peak incidence occurs, although, even then, not more than 15 per cent of infected children manifest clinical signs. Once infected, the majority of people continue to carry the virus in a latent state and maintain an almost constant level of circulating antibodies. It has been shown that the level of antibodies may fall after a primary infection, and several subclinical re-infections may occur before a stable antibody level is established. Carriers may distribute virus with or without the presence of a manifest lesion. The nonclinical carrier state is more common in children of seven months to two years of age than in adults. Although infection is usually spread subclinically, rare instances of institutional or familial outbreaks of stomatitis have been described. Lack of sufficient contact or unusual resistance leaves a small percentage of the population uninfected with the virus during childhood, thus accounting for the uncommon primary clinical infections of adults. It seems probable that close proximity is required to introduce the virus; for instance, sexual contact is associated with infection in adults. Trauma is a factor in some cases of stomatitis (e.g., teething) and in primary infections of the skin.

**Pathology.** The pathologic changes vary with the tissue infected. In general, a specific lesion is characterized by the presence of intranuclear inclusion bodies. These are

homogeneous masses lying in the midst of a severely disorganized nucleus in which the basichromatin has margined to the nuclear membrane. In the neighborhood of the specific lesion there is always evidence of an acute inflammatory reaction. In the *skin and mucous membranes* the typical lesion is a unilocular vesicle. This is formed by breakdown of epidermal cells which have undergone ballooning degeneration. In the skin there is a tense vesicle with the roof cells formed by the outer cells of the prickle cell layer and the keratinized cells beyond. Ballooned epithelial cells containing intranuclear inclusions can best be seen at the margins of the vesicle. The vesicular fluid contains shed infected epithelial cells, including multinucleated "virus" giant cells, and leukocytes. There is no necrosis. In the corium there are dilatation of capillaries and infiltration with both mononuclear and polymorphonuclear cells. In the mucous membrane, owing to maceration, there is early leakage of the vesicular fluid, resulting in a collapsed vesicle, mainly filled with fibrin, the roof cells of which are edematous. These form the gray membrane seen over the lesion. *In the brain* there are petechial hemorrhages and some areas of necrosis in the cortex and subcortical white matter; in the meninges there is congestion and infiltration with mononuclear cells. In the neighborhood of these areas, cells containing characteristic inclusion bodies are found. There is vascular engorgement and perivascular cuffing with lymphocytes. In *disseminated herpes* large areas of necrosis occur in the liver, lungs, adrenal cortex, kidneys, spleen and bone marrow which contain cells with characteristic inclusions.

**Clinical Laboratory Data.** No specific diagnostic aid is obtained from laboratory examinations, other than from viral tests (p. 384). There is a moderate polymorphonuclear leukocytosis in acute herpetic gingivostomatitis, eczema herpeticum and meningoencephalitis. In meningoencephalitis there is a cellular increase in the cerebrospinal fluid up to 1000 cells per cubic millimeter, most of which are lymphocytes; the protein level is elevated, and the sugar is within normal levels. Characteristic giant cells may be found in scrapings from fresh lesions of the skin or mucous membrane.

**Diagnosis.** The diagnosis is based on any two of the following: (1) a typical clinical picture; (2) isolation of the virus; (3) development of specific neutralizing antibodies; (4) demonstration of characteristic cells or

histologic changes in scrapings or biopsy material.

**Course and Prognosis.** Primary infection with the herpes virus is a self-limited disease, usually lasting one to two weeks. Fatalities may occur in the newborn or from meningoencephalitis or severe eczema herpeticum, but the prognosis is usually good. There may be frequent recurrent attacks, but they seldom cause more than a temporary inconvenience, except in the eye, where they may eventually cause scarring of the cornea and blindness.

**Treatment.** There is no specific therapy, but symptomatic and supportive therapy are of great importance. In infants, especially, eczema herpeticum and stomatitis may lead to severe dehydration and shock, requiring replacement of fluids and electrolytes. The use of antibiotics is of value to prevent or treat secondary infections. Application of one of the cationic detergents such as Ceepryn 1:4000 solution to the vesicles or its use as a mouth wash may be helpful; 2.5 per cent suspension of Aureomycin, used as a mouth wash, may relieve pain in older children. Pontocaine, 1 per cent, may be applied to the lesions in the mouth of infants before eating, if this can be done easily, or benzocaine lozenges may be chewed by older children.

The intake of food and fluid must be facilitated by acquiescing to the child's whims. Ice-cold fluids or semisolids are often accepted when other food is refused. Frequent recurrences may be the result of emotional disturbances, which may respond to psychotherapy.

The treatment of the ocular manifestations should be in the hands of a skilled ophthalmologist. *Cortisone must not be used*, since corneal perforation is a sequel.

**Prophylaxis.** Children with eczema should be kept from contact with manifest herpetic infection.

#### VARICELLA AND HERPES ZOSTER

Recent work of Weller and his co-workers has clearly confirmed the earlier suggestions that these two diseases are different clinical manifestations of the same etiologic agent.

Evidence of the identity of the two is based on the following factors: (1) *Epidemiologic*. Since the observations of Bokay (1888) there have been frequent reports that exposure of susceptibles to a patient with herpes zoster could result in an outbreak of chickenpox (e.g., in a children's ward). (2) *Electron microscopic*. The elementary bodies (*Herpesvirus varicellae*) obtained from vesicles of the two diseases are indistinguishable, both being described as brick-shaped bodies averaging 210 by 238 millimicrons in diameter. (3) *Microbiologic*. The infectious agent from each disease can be grown in tissue culture of human embryonic skin and muscle, or human foreskin, maintained with bovine amniotic fluid medium, and each agent produces an identical focal area of cytopathogenicity. The agents multiply in the same way by spreading peripherally from infected cells to contiguous uninfected cells without appearing in the fluid medium. The infected cells in each instance contain intranuclear inclusion bodies characteristic of the herpesvirus group. Both agents can produce chickenpox in human volunteers, and neither agent can be transmitted to lower animals or grown in the embryonated hen's egg. (4) *Serologic*. Antibodies developing in the blood of patients recovering from varicella react equally with the agents derived from varicella and herpes zoster vesicles. These reactions have been demonstrated by means of the fluorescent antibody and the complement fixation techniques.

**Etiology.** The common causative agent is now designated as *Herpesvirus varicellae*. The reasons for different clinical manifestations of the two diseases are not completely explicable. It seems probable that varicella is the primary response of a completely susceptible host, while herpes zoster may be the response of a partially immune one; such reinfection could come from an outside source or from reactivation of the virus which has been latent.

**Pathology.** The *skin lesions* of both diseases are identical and characteristic of the herpesvirus group and cannot be distinguished from those of *Herpesvirus hominis* (herpes simplex), under which heading they have been described (see p. 493). Although not usual in cases of average severity, necrosis with hemorrhage can be found in the mucous membranes of the mouth, trachea, esophagus and intestine, where the lesions resemble those of herpes simplex.

Internally, the pathologic findings vary

somewhat in the two diseases. In fatal cases of *varicella* intranuclear inclusions can be found in the endothelium of the blood vessels; the vessel walls may actually undergo necrosis. The wide distribution of these lesions suggests that the infection is blood borne. Intranuclear inclusions have also been found in most organs of the body, including the salivary glands, the nervous system, and in the cells of the myenteric plexus of the stomach and intestine. In the brain perivenous demyelination occurs similar to that of other postinfectious encephalitides; necrosis of nerve cells and leptomeningitis have been described. In *herpes zoster* the characteristic lesions are in the nervous system, particularly in the dorsal root ganglia. Early in the disease the cells of the dorsal ganglia of the affected dermatome contain intranuclear inclusions. Shortly thereafter the ganglia show only necrosis of cells, sometimes associated with hemorrhage. As the disease progresses evidence of inflammation and degeneration is found in the posterior roots and in the peripheral portions of the nerves. Unilateral and segmental necrosis of the nerve cells in the posterior horn may be found (cf. poliomyelitis, which involves the nerve cells of the anterior horn). Leptomeningitis occurs in the region of the involved nerves. Intranuclear inclusions have been found in the sympathetic ganglia, the neurilemma cells of the nerve twigs in the corium and in the myenteric plexus.

## VARICELLA

### (CHICKENPOX)

Varicella is characterized by the appearance on the skin and mucous membranes of successive crops of typical vesicles generally accompanied by a mild constitutional reaction. William Heberden in 1767 was the first to distinguish chickenpox from smallpox. The term "chickenpox," derived from *cicer*, a chicken pea, was introduced by Morton at the end of the seventeenth century.

**Epidemiology.** Varicella is extremely contagious, and therefore its incidence is mainly during childhood. The most common age for infection is from two to six years, but it can occur at any age, including the newborn period. The disease can apparently be transmitted by direct droplet infection or be airborne in the form of droplet nuclei. Air disinfection by ultraviolet light can materially decrease the spread of the disease. Epidemics of chickenpox have been initiated by exposure to herpes zoster. Patients are in-

FIG. 154. Skin lesions of chickenpox. Note the varying stages of development (macules, papules and vesicles) present at the same time. (Courtesy of Dr. P. F. Lucchesi.)

fectious from twenty-four hours before to six or seven days after the eruption, at which time the vesicles have dried up. Scabs do not appear to be infectious. Second attacks are exceedingly rare, although over 70 per cent of patients with herpes zoster have had chickenpox. In epidemics featuring both zoster and chickenpox, the former tends to appear in older members of the population, whereas the latter tends to occur in children.

**Clinical Manifestations.** The incubation period varies from eleven to twenty-one days, and is between thirteen and seventeen days in the majority of instances. At the end of the incubation period prodromal symptoms, except in the mildest cases, precede the characteristic rash by twenty-four hours. There may be slight fever, malaise or anorexia, accompanied at times by a scarlatiniform or morbilliform rash. It is characteristic of the specific rash to appear rapidly. Typically, it begins as crops of small, red papules which almost immediately develop into clear, often oval, "teardrop" vesicles on an erythematous base. These vesicles are usually not umbilicated. The contents become cloudy within about twenty-four hours. The vesicles are easily broken and become scabbed. Occasionally they dry before becoming cloudy. Except for the mildest type of case in which few lesions occur, crops of widely scattered vesicles continue to erupt for three or four days, starting on the trunk and later spreading to the face and scalp, with minimal, if any, involvement of distal parts of the extremities. There is some tendency for the lesions to be concentrated in areas of skin pressure or irritation, but not to the same extent as in smallpox. Characteristically, at the height of the disease the eruption consists of papules, early and late vesicles, and crusts present at the same time (Fig. 154). Pruritus is a con-

stant and annoying characteristic of the rash. Vesicles may also be found on mucous surfaces and are common in the mouth, where they may resemble the lesions of herpetic stomatitis. Less commonly, lesions are found on the genital mucous membranes and on the conjunctiva and cornea, where they are potentially dangerous to sight. Rarely laryngeal involvement has been recorded.

Generalized lymphadenopathy occurs, and enlargement of the suboccipital and posterior cervical nodes may result from secondarily infected scalp lesions.

The disease varies in severity from patients with few lesions and little evidence of systemic illness to those with many hundreds of lesions who may be seriously ill with temperatures ranging from 103° to 105° F. Systemic manifestations occur only during the first three to four days, when the rash is erupting. The rash rarely coalesces and rarely becomes gangrenous or hemorrhagic. Bullous lesions may occur.

Recovery from the disease occurs with the development of circulating antibodies which become detectable between four and seven days after appearance of the exanthem. The level of antibodies reaches a peak about the end of the third week and then declines, so that after five years it is low.

**Laboratory Data.** There may be a mild leukocytosis, but no specific cytologic or serologic changes have been described. Scraping of the floors of fresh vesicles will reveal the presence of virus giant cells (see Herpes Simplex, p. 494).

**Diagnosis.** This is not difficult in the average case. Most important is the distinction between chickenpox and smallpox, which may be exceedingly difficult in patients suffering from mild smallpox or severe chickenpox. The following clinical points should be borne in mind: (1) The rash of chickenpox begins on the trunk and spreads toward the periphery, while that of smallpox tends to spread from the periphery toward the trunk. (2) The lesions of smallpox tend to be most frequent in areas of pressure or tightness of the skin, as over the bridge of the nose and the wrist, or at the belt line, whereas those of chickenpox do not have this tendency to the same extent. (3) The lesions of chickenpox are more superficial and are not umbilicated, whereas the lesions of smallpox tend to be deeper and more "shotty" to the touch and are usually umbilicated. (4) The lesions of chickenpox are present in all stages of development at a given time, whereas those of

smallpox are more or less in the same stage at each phase of the disease. (5) The prodromal symptoms of chickenpox are short (one to two days) and usually mild; those of smallpox are longer (three to four days) and may be severe with high fever which drops with the appearance of the rash.

**Complications.** These are rare, and can be considered under three categories. (1) *Bacterial infection* was the most common in the preantibiotic era when streptococci and staphylococci, introduced by scratching, resulted in erysipelas, furuncles and septicemia. (2) The location of the lesions can be important; vesiculation of the larynx may result in laryngeal edema, and of the cornea in discoid keratitis. (3) The severity of the *viremia* determines the systemic pattern. Pneumonitis of an interstitial variety is usually found in fatal cases, and mostly in adults. Roentgenographically it may appear as a bilateral nodular infiltration; in nonfatal cases it clears with the skin lesions. Myocarditis has also been reported. Central nervous system involvement can manifest itself in various ways, such as meningoencephalitis, with fever, changes in sensorium and convulsions; acute cerebellar ataxia, and optic neuritis with temporary loss of vision. Neurologic manifestations may appear from three days before to twenty days after the appearance of the rash. The mortality in patients with neurologic manifestations is 5 to 11 per cent. Among those that recover sequelae are few. The cerebrospinal fluid may be normal, although occasionally there is a mild lymphocytosis.

The *increasing use of steroids* has introduced a hazard previously unknown. Patients who contract chickenpox while on steroid therapy are not able to develop antibodies and therefore run the risk of a prolonged or fatal illness in which involvement of the central nervous system, lungs and other viscera occurs.

**Prognosis.** The prognosis is good; fatalities are rare in childhood, except in children under steroid therapy.

**Treatment.** There is no specific treatment. Symptomatic treatment should be directed to alleviating itching and preventing secondary bacterial infections. Scratching deepens the superficial lesions, so that the corium becomes involved and scarring results. The fingernails should be kept short and clean, and infants should wear mittens. The child's clothing and bed linen should be changed daily, and a soap and water bath once or twice daily is

indicated to diminish the risk of bacterial infection. Itching may be relieved by starch baths and calamine lotion (U.S.P.), to which 0.25 per cent menthol is added. Sedation should be used as necessary. Treatment for secondary infection should be with systemic antibiotics, although antibiotics infrequently used systemically may be applied in ointments (e.g. polymyxin, bacitracin).

If the patient is on steroids at the time of his infection, the dose should be reduced to that amount which would provide him with approximately his physiologic requirements (i.e., 1 mg. of cortisone per kilogram per day).

**Prophylaxis.** There is no reliable and generally applicable method of prophylaxis. Gamma globulin is ineffective in protecting susceptibles. Convalescent serum taken within the first six months after onset of the disease contains a high level of antibodies and should be effective, but is impracticable for general use. Ultraviolet light disinfection of air will reduce the incidence of the disease in schools, but it is important to remember that the disease is much milder in children, and no generalized attempt to reduce the incidence of the disease during childhood should be undertaken.

#### HERPES ZOSTER (SHINGLES)

Herpes zoster is an acute infection characterized by crops of vesicles, usually confined to a dermatome and accompanied by neuralgic pain in the area of the affected dermatome. The clinical features of the disease have been known from antiquity.

**Epidemiology.** Herpes zoster is relatively uncommon under ten years of age, after which its incidence increases steadily with each succeeding decade. Second attacks of zoster are rare, less than 1 per cent in one study of 206 patients, but a history of a previous attack of chickenpox is to be expected. The severity of the disease increases with age. There is no sex or race predilection. The disease is classified as spontaneous (primary) and symptomatic (secondary), depending upon whether there seems to be a trigger mechanism such as trauma, leukemia or administration of heavy metals.

**Clinical Manifestations.** Herpes zoster has a pre-eruptive and a post-eruptive phase. In the last days of the incubation period, which appears to be from seven to twenty-one days, the patient usually has pain and tenderness along the involved dermatome. There is often

FIG. 155. Herpes zoster. (Courtesy of Dr. Carroll S. Wright.)

generalized malaise and fever. Within a few days a crop of red papules appears on the skin of the dermatome; the individual lesions quickly vesiculate (Fig. 155), become pustular, dry up and scab in the course of five to ten days. The lesions tend to appear first at a point nearest the central nervous system. Thus, in the common thoracic zoster, the dorsal part of the dermatome supplied by the shorter posterior branch of the intercostal nerve is usually involved first. Successive crops of lesions continue to appear for seven days, extending along the course of the nerve. The eruption clears in seven to fourteen days in over 90 per cent of patients under twenty years of age, but when vesicles continue to appear for seven days, healing may be delayed up to five weeks. The lesions, except in rare instances, are unilateral. Fever, pain and tenderness usually continue throughout the period of progression. The regional lymph nodes are invariably enlarged. Secondary bacterial invasion of the vesicles may occur. Under the age of twenty years almost 90 per cent of patients have involvement of dermatomes between the second dorsal and second lumbar areas. However, cephalic zoster, involving the fifth and seventh cranial and the upper three cervical nerves, which occurs in over 30 per cent of older patients, may also occur in children.

Infection associated with the distribution of the fifth nerve may involve the cornea (zoster ophthalmicus) and may lead to permanent damage; involvement of the maxillary and mandibular divisions results in lesions of the tongue and fauces; of the geniculate ganglion, in vesicles on the external ear, often accompanied by paralysis of the seventh nerve (Ramsay Hunt syndrome). Rarely paralysis

may accompany sensory changes elsewhere. In children chickenpox may occasionally manifest itself early in a dermatomic distribution shortly before the rash becomes generalized. Rarely in elderly adults true zoster with prodromal pain may be followed in a few days by a generalized rash.

**Laboratory Data.** Examination of the cerebrospinal fluid often reveals a mild lymphocytosis. Scrapings of the floors of vesicles in their initial stage will reveal virus giant cells (see Herpes Simplex, p. 494).

**Diagnosis.** Diagnosis may be difficult before development of the rash; the pain may resemble that of pleural or peritoneal origin, depending on the site of the lesion. Once the rash has appeared, its distribution and characteristics along with the pain make the diagnosis relatively simple. Occasionally, herpes simplex may simulate the distribution of zoster.

**Course and Prognosis.** In children the course is usually mild, and the ultimate prognosis is good.

**Complications.** Postherpetic pain does not occur in children. Keratitis and uveitis may follow fifth nerve involvement, and secondary bacterial infection is possible in any of the lesions.

**Treatment.** There is no specific therapy. Symptomatic treatment consists in preventing, as far as possible, secondary bacterial infection by cleanliness and prevention of scratching (see Varicella). If infection has occurred, suitable systemic or local antimicrobial therapy should be considered. Pain, seldom a serious problem in children, can usually be controlled with aspirin and codeine.

Steroid therapy is of value in the treatment of zoster ophthalmicus, in sharp contrast to the danger of its use in ophthalmic infection with the virus of herpes simplex. Treatment should be by an ophthalmologist.

**Prophylaxis.** The possibility that herpes zoster may follow exposure to chickenpox should be kept in mind. Conversely, since chickenpox can follow exposure to herpes zoster, it is unwise to admit to an open ward a child suffering from the latter disease.

Certain Viruses That Produce Intranuclear Inclusion Bodies in Man. Harvey Lectures 1956-57. New York, Academic Press, Inc.

## SMALLPOX

(VARIOLA)

Smallpox is an acute communicable viral disease characterized by a papulovesicular, pustular rash and usually by severe systemic symptoms. Vaccination, introduced a century and a half ago by Jenner, has provided a method of control. There appear to be two stable types of smallpox virus, variola major and variola minor, which usually can be distinguished by the severity of the disease they cause.

**Etiology.** The smallpox virus is stable. It can be dried under relatively unfavorable conditions and remains viable for months, as, for example, in house dust. The virus is a typical "pox virus," the elementary body being flattened and brick-shaped with a central mound-like protrusion. It measures on an average 244 by 302 millimicrons (*cf. Herpesvirus varicellae*). The virus grows readily on the chorio-allantoic membrane, where it produces characteristic pocks. In the rabbit it produces a keratoconjunctivitis after corneal inoculation (Paul's test).

**Epidemiology.** The disease is transmitted readily to susceptibles, probably by way of the respiratory tract. Fomites and letters can also spread the disease. The finding of elementary bodies in the crusts of lesions and on the bedclothes of a patient supports the air-borne theory. No age or sex is immune, but the colored races appear to be more susceptible than the white. Second attacks are extremely rare. Smallpox epizootics in monkeys have been reported in association with epidemics in human beings, and the virus can be transmitted to this host experimentally. The great danger of spread of the disease is from mild sporadic cases which may go unrecognized; such cases may be misdiagnosed as chickenpox. Laboratory assistance should be sought whenever there is suspicion of smallpox.

**Pathology.** Specific changes are found in the skin, mucous membranes and many of the organs. The typical skin lesion starts with changes in the capillaries of the corium and is characterized by dilatation, endothelial proliferation and perivascular mononuclear infiltration. In the adjacent epidermis the cells swell and the characteristic Guarnieri bodies make their appearance. These are spherical

bodies lying close to the nucleus, consisting of collections of virus elementary bodies, and range in size from 2 to 8 microns; they are seldom seen in routine sections. The swollen cells rupture, forming a vesicle divided into lobulations by thin septums of partially ruptured cellular membranes and thicker septums formed of the resistant ducts of sweat glands. The cells beneath the vesicle undergo a ballooning type of degeneration. As the vesicle enlarges through involvement of neighboring cells, it extends to the corium. The characteristic early umbilication is caused by edema and enlargement of the degenerating cells at the margin of the vesicle and by proliferation and thickening of the epidermal layer. Umbilication disappears as the fluid increases, but reappears as desiccation and crusting begin. Healing occurs without scarring except on the face, where necrosis of sebaceous glands characteristically occurs, and in other areas where there has been secondary bacterial infection.

In the mucous membranes of the respiratory and digestive tracts, changes occur coincidentally with those of the skin and consist initially in localized and then diffuse necrosis of the superficial cells and congestion and hemorrhage in the tunica propria. Grossly, these lead to the appearance of a diffuse pseudomembrane in the pharynx by the third or fourth day which disappears without scarring by the third week. Bronchitis and bronchopneumonia are common. In the liver, spleen and bone marrow the basic lesion appears to be in the reticuloendothelial cells and consists in necrosis and proliferation. In patients dying with hemorrhagic smallpox a decrease in megakaryocytes and in cells of the granulocytic series is seen in the bone marrow. In the kidneys of such patients there is an interstitial nephritis. An orchitis occurs during the papulovesicular stage, consisting in hyperplasia of the vascular endothelium followed in order by necrosis of the interstitial cells and of the seminiferous tubules. In boys the lesions resemble ischemic infarctions.

**Clinical Manifestations.** The typical case of smallpox is readily recognized, but mild cases may be misdiagnosed as chickenpox, or missed altogether. The incubation period is usually twelve to fourteen days, but may be as long as sixteen to twenty-one days in previously vaccinated persons and at times in variola minor.

**Variola major.** In a typical case the prodromal symptoms are severe and usually start abruptly. The initial clinical manifestations

include headache, chills or chilliness, aching of the back and limbs, and fever, which mounts rapidly to 106° or 107° F. In children there may also be vomiting, drowsiness, convulsions or coma. Often delirium occurs, and the patient is prostrated.

During the first two days transient rashes are common, which may resemble scarlet fever or measles or may be petechial. They tend to be most prominent over the upper thighs and buttocks (the "bathing drawers" distribution of the French clinicians) and disappear rapidly by the third or fourth day, when the raised macules of the typical cutaneous lesion begin to appear over the face. Widespread prodromal rashes and the early appearance of macules presage a severe attack with confluent lesions.

There is usually diminution in severity of symptoms as the rash becomes papular, and the temperature may even become normal and remain so until the pustular stage, when there is usually a secondary rise. The individual lesions appear in a single crop and progress at the same rate, unlike the multiple crops occurring in chickenpox. Initially the papules are 2 to 4 mm. in diameter and are firm and "shotty." Within about twenty-four hours the size of the papules increases, and vesicles appear. They tend to be umbilicated in the early and again in the late stages. Some of the vesicles are superficial, and others are deeper and less readily recognized. A small red areola develops about each vesicle.

About the fifth or sixth day of the disease the vesicles become cloudy, and the pustular stage begins. The individual lesion has a greenish or grayish-yellow color, and an elevation slightly greater than its diameter. About the ninth day of the disease the lesions begin to dry, and the areolas disappear. They are usually crusted over by the end of the second week, and the scabs drop off about the end of the third or fourth week. The scabs persist longest on the palms and soles, where they are known as "seeds" and may have to be enucleated with a needle.

The cutaneous areas chiefly involved in the early stages are those where the skin is tight, such as the wrists and the prominences of the face; the more exposed extensor surfaces of the forearms and upper arms are then involved, leaving the more protected flexor surfaces and the axilla relatively free. The rash then spreads to the thorax. In severe cases the abdomen and the legs are heavily covered; in milder cases they may be only slightly involved. Concurrently with the skin

lesions, the mucous membranes of the mouth, eyes and often the larynx become involved.

A striking feature of the disease, in contrast to chickenpox, is the profusion of lesions on the face, including the lips, and the presence of a relatively large number of lesions on the palms and soles. When the lesions become confluent, there is considerable edema of the face, so that there is difficulty in closing the eyes and mouth. The lesions on the mucous membranes also tend to be confluent.

The degree of scarring depends on the extent and severity of the eruption, and is usually greatest on the face. Intense pigmentation of the skin persists for a variable time after the scabs have fallen. In the fatal cases death usually occurs during the second week of the disease.

*Hemorrhagic smallpox* may occur in two forms: *vesicular hemorrhagic smallpox*, in which hemorrhages occur in the lesions, although death may occur before the vesicular stage develops; and "*true hemorrhagic or black smallpox*," in which a diffuse hemorrhagic rash begins on the second or third day of prodromal symptoms, followed by ecchymoses and hemorrhages into the mucous membranes. The temperature may be subnormal, although the symptoms are severe. Death may occur before the characteristic rash of smallpox develops.

*Variola minor (alastrim)*. This form differs from *variola major* chiefly in being less severe and rarely causing death. It apparently breeds true and never develops into *variola major*; it is thought by some to be a distinct disease entity.

*Varioloid*. Smallpox modified by previous vaccination is usually termed "varioloid." Although varioloid lesions appear in a single crop and progress in a manner similar to those of more severe smallpox, they are entirely discrete, and the prodromal symptoms are mild. There is no secondary rise of temperature, and premature involution of many of the lesions occurs.

*Abortive type*. In persons who have been vaccinated shortly before exposure to smallpox a condition known as "*variola sine eruptione*" may occur. Macules or papules may involute with great rapidity, or there may be no eruption at all, and the patient has only a mild, febrile illness.

**Laboratory Data.** A neutropenia is characteristic of the early stages of the disease. In hemorrhagic smallpox this may be marked and associated with a reduction of platelets. Large lymphocytes are characteristically

present in small numbers. During the pustular stage a polymorphonuclear leukocytosis occurs. There is prolongation of the prothrombin time and a decrease in fibrinogen associated with the hemorrhagic type, probably dependent on extensive liver damage.

**Diagnosis.** Diagnosis can be made on clinical grounds in a typical case or during an epidemic. In a doubtful case the patient should be isolated and viral studies obtained.

**Complications.** Pyogenic infections of the skin and bacteremia, particularly with the *Streptococcus*, were common before the availability of antibacterial agents. An enanthem of the larynx may lead to edema of the glottis and perichondritis of the laryngeal cartilages. Bronchopneumonia occurs as a terminal event in almost all fatal cases. Rarely osteomyelitis may occur as a result of direct viral invasion or of secondary bacterial infection. In the former, pain and tenderness appear during convalescence in an afebrile patient. Roentgenographically, there is widespread destruction of bones, even in those clinically uninvolved. Healing takes place without specific therapy. Central nervous system involvement is rare; symptoms usually begin five to thirteen days after the appearance of the rash and resemble those of other postinfectious encephalomyelitides.

**Prognosis.** The case fatality rate varies with the type of the disease and the age of the patient. The rate during epidemics of variola minor is less than 1 per cent, while an overall rate of about 10 per cent may be expected in epidemics of variola major. The case fatality rate is considered to be about 5 to 6 per cent in discrete smallpox, 60 per cent in confluent smallpox and 80 per cent or over in hemorrhagic smallpox. The mortality rate is greatest in children under five years of age and in persons over forty-five years of age.

**Treatment.** There is no specific treatment, but symptomatic treatment and nursing care are of extreme importance. The patient's room should be light and well ventilated; some odor-killing device should be used. Severe cases of confluent and hemorrhagic smallpox should be treated for shock and dehydration by proper use of intravenous fluids, blood and plasma. Prophylactic antibacterial therapy should be given from the beginning. Nutrition must be maintained by tube feeding if necessary. Potassium permanganate baths (1:5000) or wet dressings may be helpful for extensive skin lesions of the confluent variety. Lesions of the eyes require frequent irrigation; this therapy should be supervised by an oph-

thalmologist. Crusts in the nose may be loosened with swabs moistened with oil. Rinsing of the mouth with one of the cationic detergents, such as Ceepryn or Zephiran, may be beneficial. Sedation, including morphine, should be given as indicated. In the milder cases the general methods of treatment as outlined under Chickenpox are adequate (p. 497).

**Prophylaxis.** Vaccination is the only form of satisfactory prophylaxis, although vaccinia hyperimmune gamma globulin given after exposure may modify the disease.

Patients should be strictly isolated until all the crusts have dropped off. It would seem reasonable to use available methods of controlling air-borne spread of the disease, such as oiling of bedclothes, ultraviolet light or glycol vapors; in addition, the usual isolation precautions should be taken. Fomites, books, letters, and the like, must be sterilized, preferably by heat.

In the public health management of a smallpox epidemic the following steps, scrupulously enforced, can usually be relied on to control the spread of the disease, without the need for mass vaccination with its administrative problems and potential dangers: (1) listing of contacts; (2) surveillance of contacts for three weeks for any evidence of illness; (3) vaccination of contacts, preferably within twenty-four hours of exposure. Vaccination must produce reliable evidence of a take, and must be repeated if negative or doubtful.

#### VACCINATION AGAINST SMALLPOX

The use of cowpox virus for vaccination against smallpox was the first successful de-

velopment of a method for the protection of human beings against a serious epidemic disease. Although used by Benjamin Jesty, a Dorsetshire farmer, in 1774 to protect his own family, it was Dr. Edward Jenner in 1798 who conclusively proved that the inoculation of human beings with material from cowpox led to immunity to smallpox. The relation between the cowpox used for vaccination by Jenner and the present vaccinia virus is obscure. Cowpox and variola belong to the "pox" group of viruses which affect many species of animals, each animal having its own specific pox infection which as a rule is not transmissible to another host. However, cowpox is sufficiently related to the human "pox" virus, variola, that it can and does affect man with a specific disease of the skin of the hands on close contact. Vaccinia virus, which is a stable "pox" virus distinguishable in the laboratory from cowpox and variola, has been evolved from them. The sources of vaccinia virus used in various parts of the world probably vary, some being derived from cowpox and some from variola.

**Age of Initial Vaccination.** It is preferable to perform vaccination during the first year of life. The principal advantages are as follows: (1) Constitutional effects tend to be less than at later ages; (2) encephalomyelitis is practically unknown as a complication; and (3) immunity develops before there is likelihood of exposure to smallpox. Vaccination can be performed in the newborn period, but is usually postponed until the fourth to eighth month of life. At the time of vaccination the infant or child should be in good general health. Vaccination should not be performed in young premature infants or in any child during hot weather or immediately after severe infections, nor in children with eczema, impetigo or other skin lesions which might result in secondary infections. A child who has a sibling or close contact with another child with eczema should not be vaccinated unless they can be separated for the period of activity of the vaccinia lesion or the eczematous child protected by hyperimmune gamma globulin.

When vaccination has not been performed in infancy, it should be one of the initial prophylactic procedures whenever the child is placed under medical supervision. Most states now require vaccination against smallpox before entering school. Pregnant women should *not* be vaccinated during the first trimester.

**Type of Vaccine.** The usual type of vaccine is obtained from the pulp of vesicles of vaccinated calves, which is diluted 1:5 in 50 per cent glycerin-saline solution containing 1 per cent phenol. It is distributed in capillary glass tubes. The marketed vaccine is not completely free of bacteria, but, by law, must contain less than fifty bacteria per dose and no pathogens. It is considered potent for three months if kept below 5° C., but deteriorates rapidly at room temperature. Avianized vaccine prepared from vaccinia-infected chorio-allantoic membranes of embryonated hens' eggs is equally effective.

**Site of Vaccination.** Vaccination should be performed on the skin over the insertion of the deltoid muscle or on the posterior axillary fold. The latter site is exposed to a minimum of trauma, and the scars are inconspicuous. Vaccination on the thigh is more exposed to contamination in the infant and proves more incapacitating during the height of the reaction in older persons..

**Method of Vaccination.** Although there is good evidence that there is direct correlation between protection against the disease and the number and extent of the vaccination scars, the present policy, in nonendemic areas, is to make only one inoculation. Where smallpox is endemic or after exposure, two to four sites of inoculation are advocated. The technique is as follows: The skin should be cleansed with a volatile antiseptic, e.g., ether or acetone, care being taken to avoid causing abrasions in which the virus could "take." The tube of lymph should be removed from the freezing section of the refrigerator only at the moment of use, the two ends broken off after filing, and the contents expressed on the skin by means of a small rubber bulb. Introduction of the virus can be accomplished by one of two methods. (1) *The multiple pressure method* is most generally recommended in the United States. The needle is held almost parallel with the skin and the point pressed up and down against the skin through a drop of lymph in such a way that the surface cells are picked off, thus exposing the deeper-growing cells of the epidermis to the virus. Six to ten pressures over an area of about  $\frac{1}{8}$  to  $\frac{1}{4}$  inch in diameter are usually sufficient for primary vaccination after the age of six months. In very young infants and for revaccination, however, thirty pressures are recommended. The area should show erythema, but not blood. (2) *The scratch*

*method* is generally recommended in the British Isles and consists in making a scratch, with a minimum of trauma, with a sterile needle through a drop of vaccine lymph. The scratch should be about  $\frac{1}{4}$  inch long and deep enough to get through the skin without drawing blood, although the appearance of a drop or two is of no significance.

In each method the lymph is rubbed into the site with the haft of the needle, the excess is wiped off, and the remainder allowed to dry.

**Type of Reaction.** There are, in general, three types of reaction: (1) primary take, (2) accelerated take or vaccinoid reaction, and (3) "immune" or "immediate" reaction.

**Primary take.** This is the reaction of the nonimmune person. There is little reaction at the site except a fading erythema until the third to fifth day, when a red, slightly itching papule appears. This rapidly vesiculates within about twenty-four hours and becomes surrounded by a red areola. The vesicle grows in size and becomes umbilicated and pearly-gray, surrounded by an area of erythema and induration. The reaction reaches its height about the ninth or tenth day, when the vesicle may be as much as 1 cm. in diameter, and is easily ruptured by minor trauma; the area of erythema and induration may be ten times as large. At this time the area is hot and painful, and the regional lymph nodes are enlarged and painful. There may be enlargement of the spleen. There are systemic symptoms, such as fever which starts as a low grade one at the appearance of the vesicle and increases to as much as  $104^{\circ}$  F. or higher at the peak of the reaction, when there may be chills. Headache is common, as is general malaise. These symptoms may last three or four days. There is little change in the leukocyte count. After the peak of the reaction the vesicle undergoes desiccation, the central umbilication becoming larger and darker. The scab drops off about the twenty-first day, leaving a pink, pitted scar which slowly fades to white and remains as the only evidence that successful vaccination has been performed.

**Vaccinoid or accelerated reaction.** This is the reaction of the partially immune person. The lesion goes through the same general stages as does the primary take, but more rapidly. The greater the immunity, the more rapid is the evolution. A papule may become vesiculated within two days and reach the peak of its reaction in less than a week. The size of the reaction is smaller than with

the primary take, and there are few, if any, general signs or symptoms.

**"Immediate" reaction.** This type of reaction, often termed *immune reaction*, is usually characteristic of a solid immunity, but it can also occur in a susceptible person as a result of sensitivity to virus protein. It is important, therefore, not to accept this reaction at its face value, but to test for immunity by at least one more vaccination with a vaccine of known potency. Unless there is a circumscribed, deep-seated, indurated swelling of the skin about three days after the inoculation, which then subsides without vesiculation, the person should not be considered immune.

In some persons repeated attempts at vaccination fail. It is possible that an occasional person is truly resistant, but smallpox has occurred after many failures to secure a vaccination take. Probably such factors as potency of virus or technique of application are responsible for most of the failures.

**Revaccination.** Infections with smallpox are almost unknown within five years of successful vaccination. For routine purposes, therefore, revaccination should be performed every four years (leap year routine). In addition, revaccination must be performed whenever there is contact with a case of smallpox. Under these circumstances a positive "take" is of such importance that at least two "insertions" should be made. The important factor is the time of appearance of the reaction, so that every effort should be made to use potent material and get good contact with the appropriate skin cells. Local skin immunity to vaccination can exist without systemic immunity; so the site of revaccination should be at a location other than the original one.

**Care of Site of Vaccination.** Maintenance of dryness and a free flow of air about the vesicle is essential. Shields should never be used. A relatively sterile surface may be maintained on the entire area surrounding the reaction by sponging gently with alcohol at least twice daily, being careful to leave the surface of the vesicle intact. If the vesicle ruptures because of excessive tension of trauma, the area should be sponged with alcohol three to four times daily and loosely covered with a piece of gauze attached to the skin above and below by adhesive tape placed well outside the indurated area. When the dressing is changed, it should be cut off and the fresh one taped on over the original adhesive tapes. These should not be removed

FIG. 156. Eczema vaccinatum.

until the inflammation has subsided, so that secondary vesicles in the adhesive abraded areas are avoided.

### COMPLICATIONS

**Pyogenic Infections.** As a result of scratching or neglect, the vaccination site can become contaminated with various pathogens such as staphylococci and streptococci and give rise to cellulitis, scarlet fever or septicemia. The size of the scar is always increased by such contamination. Vaccine lymph can be contaminated with tetanus spores; however, tetanus has occurred only when a tight shield or other occlusive dressing has been applied so as to exclude air from the vaccination site.

**Nonspecific Skin Rashes.** These rashes appear to be due to hypersensitivity to virus protein and fall into the category of erythema multiforme. They usually appear seven to eleven days after the inoculation, and most frequently have a maculopapular, urticarial or papular form, but occasionally characteristic iris lesions and bullae may occur. The mucous membranes may be involved, and the picture then is one of erythema multiforme pluriorificiale, and the patient may be seriously ill. Such rashes have been noted in one of 4000 to 5000 vaccinees.

### COMPLICATIONS RELATED TO THE VIRUS

**Multiple or Unusual Sites of Vaccination.** By means of scratching, the virus can be spread by auto-inoculation to abrasions in other parts of the body. Occasionally, vaccination by contact with a vaccinated person occurs in unusual sites such as the lip, tongue, penis, vulva, or on traumatized skin anywhere.

**Generalized Vaccinia.** This is fortunately rare, occurring in about one in 100,000 vac-

inations. Three clinical categories are recognized: (1) *Generalized vaccinia* per se due to a slow development of antibodies. It varies in severity and duration. In some patients satellite vesicles keep appearing about the primary inoculation for a few days to several weeks after the usual time of antibody appearance (seventh to tenth day). Viremia, which is not demonstrable after uncomplicated vaccination, occurs, and other scattered lesions may be found in distant parts of the body. In most patients antibodies eventually appear, and the patient recovers. (2) *Prolonged or progressive vaccinia, or vaccinia gangrenosa.* In such instances the patient is incapable of making antivaccinal antibodies at all. There is spreading necrosis at the site of the vaccination, and metastatic necrotic lesions occur throughout the body, including the bones, death ensuing after many weeks or months of illness. Some of these patients have agammaglobulinemia. (3) *Eczema vaccinatum.* Inoculation of vaccine virus into a wide area of traumatized skin results in a widespread "take" with subsequent viremia. These patients are covered with umbilicated vesicles, and the mortality in infants may be as high as 30 to 40 per cent. The picture may resemble that of eczema herpeticum (see p. 491), from which it must be distinguished by the absence of recurring crops of vesicles, by epidemiologic factors, by history of contact with a vaccinated person or a primary take, and by suitable laboratory techniques.

**Postvaccinal Encephalomyelitis.** This is one of the postinfectious encephalitides. It appears usually eleven to fourteen days after vaccination, but tends to appear in less than ten days in infants. The clinical pattern varies and may be mainly encephalitic, encephalomyelitic, myelitic or meningitic. It has an incidence of approximately 1:100,000 vaccinations in the United States, although its incidence is reported at higher rates in parts of Europe. The highest incidence of morbidity and mortality is in children ranging in age from five to fifteen years; 10 per cent of cases and 20 per cent of deaths have been in infants under two years of age. It is rare under one year of age. The case fatality rate is approximately 50 per cent, most of the deaths occurring in patients with the encephalitic pattern. There is no evidence that a particular batch of vaccine lymph is involved, and there appears to be no correlation with the size or severity of the local reaction or the number of inoculations. Encephalitis ap-

pears to be less common and less severe after revaccination than after primary vaccination.

**Treatment of Complications.** Bacterial complications should be treated with appropriate antibiotics. Absence or delay of antibody production can be overcome by administration of hyperimmune vaccinal gamma globulin. This can be given as a single dose of 0.6 ml. per kilogram prophylactically to contacts with eczema or to eczematous subjects at the time of vaccination, if vaccination is mandatory. For therapy of generalized vaccinia per se a similar dose is usually sufficient. For eczema vaccinatum one or two treatments may be required. For progressive vaccinia doses must be repeated every week or two until healing is proceeding favorably and vaccinia virus can no longer be demonstrated in the lesions.

## MUMPS

### (EPIDEMIC PAROTITIS)

**Definition.** Mumps is an acute contagious viral disease characterized by painful enlargement of the salivary glands, chiefly the parotids, and by a constitutional reaction.

**History.** Mumps was recognized as early as the fifth century B.C. by Hippocrates, who mentioned the complication of orchitis. In 1790 Hamilton also noted the orchitis of mumps and the frequent involvement of the central nervous system. Since the beginning of the twentieth century the meningoencephalitis which occurs in apparent and inapparent mumps has been fully recognized, as well as the secondary inflammation of the thymus, pancreas and ovaries. In 1945 Habel and also Levens and Enders demonstrated growth of the virus in the amniotic sac of the chick embryo.

**Etiology.** Mumps is caused by a virus that can be transmitted from filtered salivary secretions of infected persons to the rhesus monkey; injection into Stensen's ducts produces the typical swelling within five to seven days. After such reactions the monkeys are immune to the disease. On subsequent injections of active virus into Stensen's duct of the same animal, swelling of the gland

occurred within twenty-four to forty-eight hours. This is termed an immune response; swelling subsides rapidly without spreading to the opposite gland. Enders and his co-workers demonstrated that the antigen or virus reaches its greatest concentration in the parotid gland of the monkey approximately three days before the usual parotid enlargement of mumps.

The virus is approximately 90 to 135 millimicrons in diameter and passes through Berkefeld V and N filters. It can be readily grown in the amniotic sac of the chick embryo and after several passages is present in large amounts in both the amniotic and allantoic sacs. It may also be grown in tissue cultures of HeLa cells and of several other human or simian cells. Owing to characteristic changes in the HeLa cells, neutralization tests may be carried out with such infected tissue cultures. The test may be read in three days, and although it is the best test for immunity it is not as practical as the quicker complement fixation test. The virus also agglutinates chick erythrocytes, but inhibition of agglutination has not been so satisfactory a test for antibodies to the virus as the complement fixation test. For this test Henle, Henle and Harris used two antigens, one a small soluble antigen, S antigen, obtained best from the chick membranes and separated from the virus by ultracentrifugation; the other a large antigen, V antigen, attached to the virus. Antibodies to S antigen in practically all instances appear first and rise to a considerable titer before the appearance of anti-V antibodies, then usually disappear within six to twelve months from the time of onset of mumps. The anti-V antibodies, appearing later, increase to a similar extent and decrease in four to six months to a level of 1:4 or 1:8, and tend to remain at such a level through life in most persons who have had apparent or inapparent mumps. By the use of a single specimen of serum obtained during or after the occurrence of suspected mumps or mumps meningoencephalitis, it is usually possible to determine by these two antigens the presence of active or recent mumps infection.

A skin test using antigen obtained from inactivated infected monkey parotid gland or preferably from chick allantoic fluid has been developed by Enders and his co-workers. It becomes positive two to three weeks after the onset of mumps. In character, time of response, and information obtained, this reaction is similar to the tuberculin test; a

reaction is not considered positive unless its diameter is at least 10 mm.

**Epidemiology.** The disease is worldwide, occurring endemically and also epidemically in the late winter and spring at approximately seven- to eight-year intervals. The sexes are equally susceptible. Transplacental immunity is apparently effective in infants up to about the sixth or seventh month of age.

By means of the complement fixation test, it has been demonstrated that a considerable number of persons have subclinical or inapparent infections. Furthermore, it is estimated that there is no enlargement of salivary glands in about 50 per cent of cases of mumps meningoencephalitis, and orchitis in adult men is not infrequent as the sole localized manifestation of mumps. In both world wars epidemics of parotitis involved mainly men from rural areas.

Far more intimate contact is required for the spread of mumps than of measles and chickenpox. Each new case of mumps infects only a small number of the susceptible population, so that epidemics of mumps tend to follow a pattern of slow rise and slow fall. Air-borne spread of the mumps virus is probably much less common than transmission by direct contact, fomites or droplet hits. Subclinical or inapparent cases must spread the disease in many instances. The portals of entry are probably the mouth, nose and eyes.

The person with mumps apparently becomes infective a few days before and remains infective during the entire period of the swelling of the glands. Thus quarantine should be maintained for about ten days from the beginning of the swelling.

Inasmuch as immunity is usually permanent, and in view of the far greater tendency of adult males to suffer epididymo-orchitis, with the attendant danger of sterility, planned exposure of boys to the disease before puberty would appear to be a sensible procedure. Atrophy of the testicle follows pressure necrosis because of lack of elasticity of the tunica albuginea, which will not permit the inflamed testicle to swell. The ovary has no such limiting membrane and can swell in the presence of inflammation and edema. Thus sterility secondary to mumps occurs at times in men, but probably not in women.

**Pathology.** Much of pathologic data is from infected monkeys; the changes in man, however, appear to be similar. The salivary ducts are swollen, edematous and obstructed,

and the acinar epithelium shows cloudy swelling and a tendency to necrosis. Both fibrinous and serous interstitial exudates are present. The tubules and glandular epithelium show edema and an extensive infiltration of leukocytes with a desquamation of epithelial cells. In the involved testes, congestion, small hemorrhages and necrosis of the epithelium in the seminiferous tubules occur, with interstitial tissue changes similar to those in the parotid. Pancreatic involvement results at times in islet degeneration and fat necrosis, as well as in the interstitial changes mentioned.

**Clinical Manifestations.** The incubation period approximates seventeen to twenty-one days. In large epidemics the cases may be divided roughly into five groups: (1) those with a short course whose signs and symptoms are insignificant; (2) those in which the disease is full-blown with salivary swelling, but no complications; (3) those with severe mumps with the complications of epididymo-orchitis or meningoencephalitis, or both; (4) no apparent symptoms, but with typical responses of antibodies; and (5) those with meningoencephalitis or orchitis without involvement of the salivary glands. Approximately 75 per cent of all cases of apparent mumps in children belong to the full-blown type without complications. Involvement of the gonads is rare before puberty.

The average case in children has a prodromal period of one to two days, with fever, anorexia, headache, vomiting and generalized aches and pains. The headache is often particularly marked and is probably associated with mild meningoencephalitis. Finkelstein in successive cases of apparently uncomplicated mumps found a large number with pleocytosis. The temperature usually rises slowly to 102° or 103° F. as the disease becomes full-blown, but at times there is only slight or no fever. In cases complicated by epididymo-orchitis or meningoencephalitis, or both, temperatures of 105° or 106° F. are occasionally seen.

After the prodromal period one or both glands begin to enlarge. Mumps is bilateral in approximately 70 to 80 per cent of instances. A few days to a week or more may intervene between the swellings of the two sides. A distinctive "puckering" feeling appears at the angle of the jaw in the early stage and is increased by application to the tongue of sour liquids such as lemon juice or vinegar. This sign, when present, may be of considerable assistance in diagnosis. The

swelling of the gland is also distinctive in that a brawny type of edema occurs about the gland, the borders of which are not discrete, in contrast to the discrete swelling typical of lymphadenitis, in which the node is usually easily outlined. The lobe of the ear is in the center of the swelling, which usually cannot be separated by palpation from the angle of the jaw. Pressure is painful, and it is often difficult to open the jaw. The swelling reaches its maximum in about three days, remains at its peak for approximately two days, and then slowly recedes. The extent of the swelling varies considerably, but at times is sufficient to distort completely the outline of the face and head. The submaxillary and sublingual glands may be involved separately or with the parotids in any combination.

During the prodromal phase slight redness of the orifices of Stensen's or Wharton's ducts, when present, has diagnostic significance. The amount of saliva is usually unchanged, although the mouth may be dry or salivation may be extreme. Gellis described a few cases with edema over the upper part of the sternum apparently due to pressure on the lymphatics in the neck.

In uncomplicated mumps, as a rule, there is a low white blood cell count, with a relative lymphocytosis. In meningoencephalitis orchitis the white cell count is a little higher with a somewhat larger number of polymorphonuclear cells.

**Diagnosis.** Other types of infection in the parotid gland, often pyogenic in origin, are most frequently confused with parotitis. The possibility of a small stone in Stensen's duct at times must be ruled out. The method of distinguishing lymphadenitis is discussed under Clinical Manifestations. Mixed tumors of the parotid gland and Mikulicz's syndrome must also be considered in the diagnosis. The value of the complement fixation test has been discussed under Etiology.

**Complications.** Epididymo-orchitis almost never occurs before puberty, and oophoritis is even less common. Approximately 80 per cent of the cases of epididymo-orchitis appear during the first eight days of mumps, but a few occur a considerable time after the parotitis has subsided. It appears to make little difference whether patients are kept in bed during convalescence. The onset is usually with a chill, recurrence of fever and swelling of the testis. Pain over the renal area or in the lower abdomen, bilateral or unilateral, may precede or accompany orchitis. Occasionally this pain, if on the right

side, may suggest appendicitis. Support of the testes and application of an ice bag are of assistance. Incision of the tunica albuginea is highly effectual in the relief of pain and probably in the prevention of atrophy and loss of function.

Meningoencephalitis is a frequent complication and may occur in the absence of parotitis. The severity is not indicated by the number of cells in the cerebrospinal fluid. The symptoms are similar to those of other types of encephalitis (see p. 547). If death does not occur in the early stages, and it rarely does, recovery may be fairly rapid and is usually complete.

Other nervous complications include multiple neuritis, transverse myelitis and ascending or Landry's type of paralysis. Subarachnoid hemorrhage and hemiparesis with grossly bloody cerebrospinal fluid have been reported. Unilateral deafness is a rare complication.

Mumps pancreatitis is also extremely rare in children, although many complain of epigastric pain and vomit. In such cases it is difficult to be certain whether the pancreas is involved. In doubtful cases determination of serum or urine amylase has been of assistance. Occasionally the thymus, thyroid and breast are involved. Pericarditis, myocarditis and involvement of the spleen, prostate, kidneys and vulvovaginal glands have also been reported.

**Prophylaxis.** The potential danger of mumps in the adult as compared to the child accentuates the need for production of permanent immunity before puberty, whether by the disease—apparent or inapparent—or by one of the methods of active immunization. Two methods are now under trial: (1) parenteral injection of formalized virus from infected chick allantoic fluid and (2) the spraying of attenuated virus into the mouth. The latter method is also being tested in infants during their phase of transplacental immunity and in persons who have previously received the formalized vaccine. The formalized vaccine has appeared to develop some degree of immunity when given in two doses of 1 ml. each, four to six weeks apart, followed by a booster dose six to twelve months later. The protection is provided in a majority of instances for at least eight months. Inapparent infection in vaccinated persons may convert a transitory immunity into a permanent one.

Passive protection by gamma globulin from convalescents or by unfractionated convales-

cent plasma or serum is of doubtful value. Gamma globulin from pooled plasma apparently is not protective.

**Treatment.** The patient should be kept in bed during the period of fever and swelling. Heat to the swollen area may be of some comfort; ice is less comfortable, as a rule. A soft diet and liquids are preferable to solid food. The use of convalescent gamma globulin appears to have some value in preventing orchitis.

## EPIDEMIC INFLUENZA

**Definition.** Influenza is an acute communicable viral disease primarily affecting the respiratory tract. It occurs in great pandemic waves usually separated by several decades, during which interpandemics or epidemics of less severity occur at two to four year intervals.

**Etiology.** Two viral agents have apparently been responsible for most of the sharp out-

breaks of respiratory infection resembling influenza since 1933: influenza A virus, identified by Smith, Andrewes and Laidlaw; and influenza B virus, identified independently by Francis and by Magill in 1940. Subsequently two additional types of influenza virus have been isolated and identified as C and D; they are apparently responsible for milder diseases than those caused by viruses A and B. Pandemic influenza, similar in worldwide prevalence, but not in severity, to that of 1918-19, occurred in 1957, starting in central China, western Europe and in certain other areas about the same time. The causative virus was shown to be a mutant strain—Asian strain—of type A influenza virus, to which immunity could not be produced by vaccines containing known strains of type A virus. Persons born before 1890 were usually found to have antibodies to the Asian strain, thus suggesting an antigenic relation of the new mutant to the virus responsible for the pandemic of 1889-90. For the first time in 1957 it was possible to determine that rapidly fatal cases in a pandemic were not necessarily the result of superimposed bacterial infection, but resulted in many instances from the antigenic quality of the virus itself.

Influenza viruses A and B are serologically distinct, but each type has a number of strains which have antigenic differences, and cross immunity has not been produced.

Preparations of virus, purified as far as possible, contain ribose nucleic acids as well as protein, carbohydrate (the polysaccharides: mannose, galactose and glucosamine units) and water. The viruses are most stable in a pH range of 6.5 to 7.9. Their infectivity is lost when they are heated to 56° C. for thirty minutes, when irradiated with ultraviolet light or when treated with formaldehyde. They will remain active when stored at 76° C. in sealed glass ampules for an indefinite period if the preparation is properly buffered. The viral bodies contain considerable amounts of toxic material.

Inhalation of the active viruses A and B by susceptible human beings will cause sharp influenzal attacks without complications, if such studies are conducted in the absence of pathogenic bacteria or with control of them by previously administered antibacterial agents. After such experimental infections and the natural infection with either virus, neutralizing and complement-fixing antibodies increase rapidly, reaching their peak within approximately two to three weeks, and

then slowly diminish to their previous levels in approximately one year. A fourfold increase of antibodies in comparative tests of acute and convalescent serums may be regarded as indicating infection with the virus tested.

The agglutination of chick red cells by both viruses and the inhibition of this phenomenon by previous addition to the viruses of an immune serum were developed independently by Hirst and Hare as a means of determining the presence and amounts of antibodies in unknown serums. By careful control (i.e., the amount of virus, the concentration of red blood cells and the titration end point) the antibody content of unknown serums can be measured by dilution of the serums to the point at which inhibition of the chick red cell agglutination no longer occurs. This method of measuring antibody formations is more exact and less cumbersome than the virus neutralization test, but not as accurate as the complement fixation test. The soluble antigen is the same for all type A strains (swine, A, A.' Asian); the soluble antigen of type B is quite different from that of type A.

In both pandemic and epidemic influenza the secondarily invading bacteria are of sufficient importance to be considered of etiologic significance, particularly since the mortality in both types of outbreak is, to an extent, dependent on such invaders. *Hemophilus influenzae*, the hemolytic *Streptococcus*, the *Pneumococcus* and the *Staphylococcus aureus* are the more frequent invaders. The last is perhaps the most serious one, owing to the frequency of antibiotic resistant strains.

**Epidemiology.** Influenza is probably the only remaining pandemic disease over which no effective control has been established. The pandemic of 1918 is estimated to have caused approximately 22 million deaths throughout the world in about three months, approximately 500 million additional persons being attacked.

Recently obtained serologic data relating to the pandemics of 1889, 1918 and 1957, together with identification of different strains of influenza A virus from various epidemics since 1930, strongly suggest, but do not prove, a pattern of recurrent outbreaks of influenza A infections which depends primarily upon mutant strains of virus and secondarily upon the accumulation of susceptible hosts, especially among the young and

middle-aged. Recurrent epidemics from the same strain may occur every three to four years following a pandemic as sufficient numbers of susceptible hosts accumulate, but a subsequent pandemic does not occur until a new mutant strain of virus again becomes widespread. The pandemic usually occurs in three waves of approximately equal incidence separated by an interval of several months, the last one being the most severe.

Epidemic influenza occurs in sharp outbreaks similar to the first wave of pandemic influenza and generally with few complications and a low mortality. The morbidity is usually about 30 to 35 per cent of the population. Epidemics usually occur in the late winter or early spring, but at times in the early winter or late fall. Epidemics from strains of A virus tend to recur every year or two, while those of influenza B thus far have recurred less frequently. They have rarely occurred simultaneously in the same geographic area. In a single epidemic the strains of virus isolated are usually closely related antigenically.

Little is known about the method of spread of either pandemic or epidemic influenza. Shope calls attention to the simultaneous occurrences of outbreaks in the pandemic of 1789-90 in places widely separated by many weeks of the customarily slow travel of that period. Such outbreaks occurred simultaneously on land and on slow sailing vessels six to eight weeks at sea.

The virus may spread by the air-borne route; whether this route is more important than the more commonly accepted ones of direct contact or direct "droplet hits" has not been determined. The viruses of influenza are in the upper respiratory tracts of patients from the first to the fifth day of disease. They have not been found in the blood stream.

Both sexes and all races appear to be equally susceptible. Young adults and children over five years of age appear to be more susceptible than infants and older persons. Experimental infection of human beings has indicated a direct relation between the height of serum antibodies and the resistance to infection. A large number of inapparent infections occur in any epidemic, as indicated by the rise of antibody titers in persons who have had no symptoms. No possible reservoir of the viruses for interepidemic survival has been found, nor have carriers been discovered. Sporadic cases may be the link between

epidemics, since the seasons of high incidence of respiratory diseases succeed each other in the two hemispheres.

**Pathology.** Uncomplicated influenza in man may be considered analogous to the disease in ferrets, in which there is a severe inflammatory reaction in the mucous membrane of the upper respiratory tract with a loss of ciliated epithelium. Regeneration in ferrets occurs by relatively rapid development of epithelium of a more squamous type over a period of several weeks with slower regeneration of the columnar epithelium. During this transitional period the epithelium is resistant to further influenzal virus infections and returns to normal status within a month or so.

In severe cases in man hemorrhages with serosanguineous exudate often occur in the pharynx, larynx, bronchi and bronchioles, with edema of the entire bronchial tree and often of the alveoli. The alveolar ducts and bronchioles may be dilated and their walls frequently covered with a hyaline membrane, which also partly or completely covers the walls of the alveoli. There is necrosis of the mucous membrane, and emphysema is usually present in localized areas.

The pathologic picture may be considerably altered by bacterial pathogens. When several different organisms are present, the pathologic changes are less uniform than when there is a single pathogen. With the *Pneumococcus* there is typically a lobular pneumonia tending to become confluent; with the influenzal bacillus there are severe destructive changes in the bronchioles and interstitial pneumonia, often leading to bronchiectasis; with the *Micrococcus pyogenes*, variant *aureus*, an overwhelming infection characterized by hemorrhagic edema and multiple pulmonary abscesses; and with the hemolytic *Streptococcus*, an interstitial reaction with hemorrhagic edema and frequently with pleurisy and empyema.

**Clinical Manifestations.** Since the symptoms of pandemic and epidemic influenza are similar except for severity and extent of complications, they are considered jointly. Experimental infections of human susceptibles have simulated the milder cases of epidemics.

The incubation period is usually about thirty-six to forty-eight hours. The onset is sudden with a chill or a chilly sensation, frequently in children with a convulsion; a sharp rise in temperature ranging from 102° to 106° F.; flushing of the face, neck and

chest; headache; vertigo; a dry sore throat; and pains in the back and extremities. A short, dry, hacking cough usually is present soon after the onset and rapidly increases in frequency and severity. It often becomes paroxysmal and resembles the cough of pertussis. In young children vomiting and diarrhea may be the principal manifestations at the onset. The accompanying prostration may be extreme and is related not only to the severity of the disease, but also to the lack of complete bed rest from the onset of symptoms. The fever is often diphasic, with the two peaks separated by a period of twenty-four to forty-eight hours.

The mucous membranes of the throat appear dry and red with no exudate; those of the nose are red, but usually there is little or no discharge except when purulent sinusitis is a late complication. The conjunctivas are injected. Epistaxis is common. The pulse is usually rapid and often weak, as are the heart sounds when the cardiac muscle is seriously affected. Often the skeletal muscles are painful on pressure, and movements of the eyeballs cause considerable discomfort.

The usual increase in leukocytes during the early stages of the disease is soon replaced by a leukopenia with a relative lymphocytosis. Often in the later stages there is a slight increase in monocytes, although complicating bacterial infection may alter this picture. Blood cultures are sterile, and the erythrocyte sedimentation rate is increased.

The milder uncomplicated cases clear almost as rapidly as they start, rarely lasting more than three or four days.

In severe infections which extend into the lower respiratory tract fine moist rales may soon be detected bilaterally, and these may rapidly spread over the entire lung area with diminution of breath sounds, or a tendency to bronchial breathing if consolidation occurs. As the cough increases in frequency it becomes productive, often sanguineous at first and later mucopurulent. Diminution of breath sounds resulting from edema of the bronchial tree and alveoli is far more common than the localized consolidation of lobular pneumonia, and frequently the breath sounds almost disappear as patchy edematous and atelectatic areas are interspersed with areas of emphysema. In the extremely severe infections which occur frequently in pandemics these changes are extensive, and the patient shows evidence of severe anoxia. Myocardial involvement results in distention of the right side of the heart, passive congestion

of the liver, and, finally, extensive pulmonary edema and cardiac failure. Death occurred frequently in the 1957 pandemic with only one quarter to one third of the lungs involved, apparently as the result of the direct toxic effect on the vital nerve centers.

When secondary bacterial infections are present, the symptoms depend to a considerable extent upon the type of organism involved, as indicated under Pathology.

**Diagnosis.** During epidemics or pandemics the diagnosis is not difficult, owing to the uniformity of the clinical manifestations. The simplest diagnostic test is that of Hirst and Hare (p. 509); when the nature of an epidemic has been established by this test, succeeding cases with a typical pattern are not easily mistaken. The complement fixation test, however, appears to be a more reliable diagnostic measure. The isolation of virus by intra-amniotic inoculation of throat washings treated with penicillin and streptomycin is helpful.

**Complications.** In few other diseases are the complications such an integral part of the severe forms of the infection. Many of them have been mentioned under Clinical Manifestations and may more properly be termed "clinical variations."

Otitis media, mastoiditis, purulent sinusitis, pneumonia, bronchiectasis, pulmonary abscess, and empyema are the more common respiratory variants of the severe infections. Less common ones are pneumothorax and mediastinitis. Rare nonrespiratory complications include hematoma from rupture of the rectus muscles of the abdomen, epistaxis, intestinal hemorrhage, polyneuritis, postinfluenzal psychoses, nephritis, subcutaneous or intramuscular abscess, endocarditis, myocarditis, pericarditis, thrombophlebitis, meningitis and hemorrhagic encephalitis. Some cases of bronchiectasis in adults possibly result from severe influenza in childhood. Chronic bronchitis and pulmonary fibrosis may also be sequels.

**Prophylaxis.** There are no known methods of increasing general resistance to influenza. Avoidance of fatigue and chilling and of large assemblies of people, however, is important. Specific resistance may apparently be increased by various types of influenzal virus A and B vaccines, including those derived from allantoic fluid, either concentrated or unconcentrated. Febrile and local reactions to the vaccines have resulted from the toxic properties of the viruses they contain and are proportional to the amount of virus N pres-

ent. In rare instances persons allergic to chick embryo proteins may have anaphylactic reactions. New strains of influenza A, i.e., A' and Asian, which have appeared recently have complicated the production of an effective vaccine, since the older strains, such as PR8, will not protect against the other prime strains of virus. Current strains can be incorporated to produce successful vaccines. The serum antibodies can be increased within seven to ten days by such vaccines; if large quantities are available, they may be useful against a pending epidemic. In general, the response to vaccines has been inversely proportional to the original level of antibodies in the person vaccinated.

Methods of disinfecting air, such as ultraviolet light, may possibly assist in preventing the spread of virus by the air-borne route within crowded spaces. Patients with influenza should not be placed in open wards without means of disinfecting the air, owing to the danger of bacterial infection from patient to patient. Isolation may be of value in preventing such complications. The value of masks in preventing the spread of secondary bacterial invaders is limited.

**Treatment.** No specific remedy is available. The use of convalescent or immune serums is still on an experimental basis. Complete bed rest from the earliest evidence of disease is absolutely essential and should be continued long into convalescence. The sulfonamide drugs and antibiotics are indicated for such complications as pulmonary abscesses, empyema and pneumonia. The fluid intake should be ample, and the quantity may be increased by use of fruit juices, lemonade and ginger ale. Acetylsalicylic acid and codeine may be used for discomfort and cough.

## RABIES

### (HYDROPHOBIA)

**Definition.** Rabies is an acute viral disease of the central nervous system which is ordinarily transmitted to man by the bite of a rabid dog or occasionally a rabid cat or a rabid wild animal. In general, it is characterized by extreme excitation, severe and painful spasm of the muscles of the pharynx and larynx at the sight of food or liquids, which accounts for the name "hydrophobia," and finally by generalized paralysis and death within a few days.

**History.** Rabies is one of the oldest recorded diseases in Europe and Asia. Democritus in 500 B.C. and Aristotle in 322 B.C. described rabies; Celsus in A.D. 100 advised cauterization of bites by rabid dogs, and Galen in A.D. 200 advised surgical excision of the bite. Apparently rabies had not occurred in North and South America before colonization.

In 1804 Zinke infected a normal dog with saliva from a rabid dog. Pasteur in 1881 to 1884 demonstrated the infective agent in the central nervous system of rabbits and named it a virus, from the Latin word for poison. There followed the development in his laboratories of the fixed virus and the study of vaccination with attenuated virus. Fermi in 1908 treated infected nervous tissue with phenol for use as a vaccine. In 1903 Negri demonstrated the inclusion bodies now known by his name. In 1921 Haupt found the vampire bat to be a symptomless carrier of the virus, a finding of great epidemiologic importance.

**Etiology.** The rabies virus is neurotropic and travels by the injured peripheral nerves

to the central nervous system. This natural virus is termed "street virus" and has a variation in incubation period which in general appears to be related to the distance of the injury from the head, the severity of the bite, and the amount of virus in the wound. The "street virus" invades the salivary glands and usually is transmitted in saliva. The "fixed virus" is the term applied to natural virus modified by repeated intracerebral passages in laboratory animals. This virus has a four-to six-day incubation period and does not invade the salivary glands. The natural or "street virus" through multiple passage in the chick embryo loses its pathogenic properties and may be used without inactivation for vaccination. The virus is about 100 to 150 millimicrons in diameter, and, although it passes through bacteria-retaining porcelain filters, it is filtered with some difficulty through Seitz EK filter pads. Although ultraviolet radiation, sunlight, mercuric chloride and formalin inactivate the virus readily, it is quite resistant to phenol and fairly so to chloroform and ether. It is killed in an hour in watery solution at 56° C., but may be readily preserved by desiccation from the frozen state.

**Epidemiology.** Two categories of rabies have been suggested by Johnson: the sylvatic, existing in wild animals; and the urban, prevalent in domestic dogs. Sylvatic rabies is well recognized among the wolves of Canada, the Arctic, and of such smaller countries as Iran, as well as among foxes, coyotes, skunks, and more recently bats in the United States, Central and South America.

Symptom complexes in animals which in the past were not associated with rabies, such as "running fits" of dogs and paralytic syndromes in dogs and other animals, may be of rabid origin. Rabies appears to be increasing among dogs in the United States, although in human beings the number of deaths annually has been less than 100. In certain areas outside the United States the paralytic form of rabies has been more frequent and may indicate a variation in the antigenicity of the virus, although immunologically all strains of virus isolated have been similar. In Trinidad both man and cattle have been infected by vampire bats, which apparently are carriers and not victims of the disease. The disease apparently has been transmitted from a rabid lactating dog to her litter by way of the milk, but there is no record of the transmission of rabies from a rabid cow to man by this same route.

**Pathology.** Fresh virus from a rabid dog will cause widespread degeneration and necrosis of neurons. Demyelination and degeneration of the axis cylinders are present in the white matter. The areas chiefly involved are the red nucleus, substantia nigra, pons and particularly the nuclei of the cranial nerves in the medulla. Here neuronophagia and infiltration with mononuclear cells are extensive. The pathognomonic change in the neuronal cytoplasm and dendritic processes is the Negri body, which is apparently an inclusion body. It has eosinophilic cytoplasm with a basophilic granular corpuscle in the center. Since the neurons of the salivary glands at times show similar changes with Negri bodies, it is conceivable that the rabies virus enters the saliva by this route.

**Clinical Manifestations.** Since prophylaxis against the disease in man depends to a great extent upon an understanding of the early manifestations in the dog, they are described first.

*In the dog* symptoms may be considered under two general types, although it is not possible to separate them completely.

1. The "furious" type results from increased excitation of the central nervous system, with fever, hyperesthesia and lack of appetite. The evidences of disease depend to a great extent upon the nature and training of the dog. The more aggressive dog will begin to snap and become excited and dangerous early in the course of the disease. The gentle dog in the early stages will more frequently seek seclusion and refuse food or will become excessively affectionate, after which it becomes agitated and restless. This is usually followed by irritability and snapping at strangers and a little later by snarling or snapping at imaginary objects and chasing and biting other animals. Finally, if free, it will run for miles, snapping at or biting all living things in its path until it falls paralyzed to the ground.

2. The "dumb" or paralytic type, despite its frequency (approximately 20 per cent), is rarely recognized by the dog's owners, primarily because no agitation or excitement is seen. The course is far more rapid, paralysis occurring in any group of muscles, but particularly in the lower jaw and in the muscles of deglutition. In such cases the tongue hangs out of the mouth, continuously dripping saliva; sympathetic persons, suspecting a foreign body in the dog's throat, may expose their hands to the infective saliva in an effort to relieve the dog. Rapidly extending paralysis soon results in death; occasionally dogs die suddenly without signs of illness, and encephalitis with Negri bodies is found at autopsy.

*In man* the incubation period is approximately four to eight weeks, but may be months and, rarely, as long as a year. It may also be shorter than four weeks when the lacerations are about the head or neck, ap-

parently because of the greater laceration and the larger amount of virus thus introduced, rather than because of short distance from the laceration to the central nervous system.

The majority of clinical cases are characterized by three stages. In the *prodromal* phase, numbness, formication, tingling, burning or a sensation of cold may be felt about the wound and along the involved nerve trunks, followed by mild excitation with irritability, restlessness, dilatation of pupils, salivation, lacrimation, perspiration and insomnia or, at times, drowsiness and depression.

In the *second* phase the excitation rapidly increases, and there is apprehension and even terror. The neck becomes stiff, and there is delirium and twitching or mild convulsive movements. At this stage the sign appears which has characterized the disease, i.e., the strangulating and intensely painful spasm of the throat at any attempt to swallow food or liquids and even at the sight of them (hydrophobia). Slight noises may initiate these spasms, and the extreme hyperesthesia of the skin also facilitates their initiation through tactile stimuli. At such times the patient is unable to breathe, and the body remains in a tonic convulsion during which death may occur. The temperature is usually elevated to 103° to 105° F., but may be considerably lower. Blood-tinged vomitus or excessive saliva may give the impression of "frothing."

Within one to three days the patient passes rapidly into the *terminal* phase with increasing paralysis, cessation of spasms, coma and death within another day or two.

The paralytic form of the disease, which is far less common, begins with numbness or severe pains in the nerve trunks supplying the involved area, followed shortly by flaccid paralysis of the part, which extends first to the opposite side of the body, and then slowly ascends in a manner similar to Landry's paralysis, terminating with involvement of the respiratory and circulatory centers.

Ordinarily, in each form there is a polymorphonuclear leukocytosis, often as great as 20,000 to 30,000 cells per cubic millimeter. The cerebrospinal fluid usually has a slight increase of protein and occasionally of cells, up to 30 to 100 mononuclear cells per cubic millimeter.

**Diagnosis.** The only organic disease for which rabies may be mistaken is *tetanus*, which has no cellular response or increase of protein in the cerebrospinal fluid and has a characteristic trismus. Another differenti-

Table 74. Indications for Specific Postexposure Treatment\*

Nature of Exposure	CONDITION OF ANIMAL		
	At Time of Exposure	During Observation Period of 10 Days	Recommended Treatment
I. No lesions Indirect contact only	Rabid	—	None†
II. Licks			
1. Unabraded skin	Rabid	—	None†
2. Abraded skin and abraded or un- abraded mucosa	(a) Healthy	Healthy	None
	(b) Healthy	Clinical signs of rabies or proved rabid	Start vaccine at first signs of rabies in animal
	(c) Signs suggestive of rabies	Healthy	Start vaccine immediately. Stop treatment if animal is normal on fifth day after exposure‡
	(d) Rabid, escaped, killed or unknown	—	Start vaccine immediately
III. Bites			
1. Simple exposure	(a) Healthy	Healthy	None
	(b) Healthy	Clinical signs of rabies or proved rabid	Start vaccine at first signs of rabies in animal
	(c) Signs suggestive of rabies	Healthy	Start vaccine immediately. Stop treatment if animal is normal on fifth day after exposure‡
	(d) Rabid, escaped, killed or unknown; or any bite by wolf, jackal, fox or other wild ani- mal	—	Start vaccine immediately
2. Severe exposure (Multiple; or face, head or neck bites)	(a) Healthy	Healthy	Hyperimmune serum immediately; no vaccine as long as animal remains normal
	(b) Healthy	Clinical signs of rabies or proved rabid	As in III, 2, (a), but start vaccine at first sign of rabies
	(c) Signs suggestive of rabies	Healthy	Hyperimmune serum immediately, followed by vaccine. Vaccine may be stopped if animal is nor- mal on fifth day after exposure
	(d) Rabid, escaped, killed or unknown. Any bite by wild animal	—	Hyperimmune serum immediately, followed by vaccine

Hyperimmune serum to be effective must be given within 72 hours of exposure.

These indications apply equally well whether or not the biting animal has been previously vaccinated.

\* Prepared by Expert Committee on Rabies of World Health Organization.

† Start vaccine immediately in young children and patients when a reliable history cannot be obtained.

‡ Alternative treatment would be to give hyperimmune serum and not start vaccine as long as animal remains normal.

ating feature of tetanus is the lack of strangulating spasms of the muscles of deglutition. Occasionally a person who has been bitten suffers a hysterical state simulating rabies, but this is not difficult to differentiate from the organic disease.

**Prognosis.** No recovery from rabies has been recorded.

**Prevention.** The most important prophylactic measure is control of dogs. In England, the Scandinavian countries and Canada, rabies has been nearly eliminated by precautions in the general handling of dogs. Stray dogs should be eliminated, and all other dogs should be muzzled, confined or on leash. A dog bitten by a rabid animal should either

be killed or isolated immediately for at least six to eight months. Vaccination of such a dog may be carried out successfully only if a sufficient number of injections is given, the customary single prophylactic injection of rabies vaccine in dogs being totally inadequate. The disappearance of a dog after biting an animal or man should be regarded with suspicion, since a dog frequently seeks seclusion before death from rabies. Suspicion should also be attached to a previously gentle dog whose behavior suddenly changes. Any dog which has bitten a person, but which has no sign of rabies, should be kept under surveillance.

Suggestions for prophylactic therapy are detailed in Table 74.

*Passive immunization* with hyperimmune antirabies serum is now accepted as an essential part of prophylaxis to be used immediately prior to vaccination. It may be that use of the serum may permit a shortening of the vaccine course from three to two weeks, thereby lessening the danger of paralytic complications.

The vaccine is usually given in doses of 2 cc. daily for fourteen days, starting immediately after the bite, or for twenty-one days if the bite has occurred on the head, neck or shoulders. It is injected subcutaneously into the abdominal wall, the area for injection being varied from day to day in order to avoid severe local reactions.

An acute myelitis with paralysis resulting from vaccination is a rare but serious complication which may be lethal. About 80 per cent of those who recover do so completely. It occurs about one to four weeks after the start of vaccination. The vaccines in which the virus has been destroyed are less likely to cause this complication than those containing active virus, though probably the reaction is due primarily to the heterologous tissue of the rabbit cord rather than to the virus itself. Adults are more susceptible than children to such myelitis.

**Treatment.** Although the usual treatment of the rabid animal's bite has been to cauterize it with fuming nitric acid, the possible advantages are outweighed by the disadvantages of pain and scarring, particularly in view of the more recent success with injection of antirabies serum in the area immediately adjacent to the wound. Bites and abrasions exposed to the animal's saliva should be thoroughly cleansed, first with soap and water, and finally with a 1 per cent solution of Zephiran chloride.

Active treatment, once the disease has developed, is of little avail. Sedatives should be used in large doses, and the patient's room should be kept quiet and dark to avoid all stimuli. Anesthesia for the convulsions is necessary as the disease progresses. Attendants should be vaccinated and must also be careful to avoid the danger of being bitten by the patient.

## YELLOW FEVER

**Definition.** Yellow fever is an acute infectious viral disease with severe constitutional symptoms accompanied by hepatitis with jaundice, hematemesis, nephritis and degenerative changes in the cardiac muscle. Although it has occurred during the summer in the temperate zones, it is essentially a disease of the tropical zones.

Immunologically the strains of yellow fever virus may not differ, but clinically a differentiation appears necessary between *jungle yellow fever* and the more common *urban yellow fever*, for which *Aedes aegypti* acts as a vector. Jungle yellow fever occurs

occasionally in man in close contact with the jungle in the absence of *Aedes aegypti*. In jungle yellow fever in South America the virus has been found in mosquitoes of the genus *Haemagogus* and in *Aedes leucocelaeus*, while in Africa it has been found in *Aedes simpsoni* and *A. africanus*.

**History.** Carlos Finlay in 1881 first suggested that the mosquito, *Aedes aegypti*, was the vector, and the classical experiments of Reed, Carroll, Agramonte and Lazear in 1900 and 1901 verified its essential role in the disease and the need for mosquito control and established the virus as the etiologic agent.

**Etiology.** The virus of yellow fever is approximately 20 millimicrons in diameter, being one of the smallest isolated. Affinity or tropism of the virus for host cells is of two main types: neurotropism, an affinity for nervous tissue, and viscerotropism, an affinity for the liver, kidney and heart. Under natural field conditions the virus is pantropic. Both viscerotropism and neurotropism of the virus can be greatly reduced by repeated passage in tissue cultures, whereas neurotropism is increased and viscerotropism practically disappears after repeated intracerebral passage of the virus in mice.

Man and the rhesus monkey (*Macaca mulatta*) are highly susceptible to the pantropic strain of virus found in the field, the severe lesions in both occurring in the liver, heart and kidneys as a result of the viscerotropic properties of the virus. In the laboratory the neurotropic strain developed from intracerebral mouse passage produces, when injected intracerebrally in the *Macaca mulatta*, a usually fatal encephalitis with absence of hepatitis and other visceral lesions. Other animals differ considerably in their susceptibilities to these viral tropic properties.

**Epidemiology.** In transmission of the more common form of the disease the aegypti mosquito bites an infected person during the first three days of the disease when the virus is circulating in the blood. After nine to twelve days of incubation of the virus in the mosquito a susceptible host is bitten who acquires the disease after a further incubation period of approximately three to six days.

Another, less common method of infection has been suggested in the laboratory without transmission by an insect vector. While the virus is circulating in the blood of monkeys it can apparently be transmitted from one animal to another through the intact skin. The passaged neurotropic virus may also be

transmitted to both mice and monkeys by intranasal instillation.

A few African outbreaks of urban yellow fever have occurred in areas contiguous to endemic areas of jungle yellow fever, such as in Nigeria in 1946. In Central America jungle yellow fever has been slowly spreading north from Panama since 1948 in epidemic form. Urban yellow fever has not been present in the Western Hemisphere since 1934 and has never been reported in the Orient.

**Pathology.** On gross appearance the body reveals severe jaundice, combined usually with petechial hemorrhages or ecchymotic areas of the skin. There may be black, bloody vomitus in the nose and mouth which is also usually present in the stomach in considerable amounts. The primary visceral changes are in the liver, which is normal in size or slightly enlarged and has a deep yellow stain.

The typical microscopic lesion of the liver is an acute, midlobular fatty degeneration and necrosis of the parenchymatous cells, with normal cells immediately surrounding the central vein of the lobule and the portal vein. The architecture of the liver is preserved, and in healing no cirrhosis occurs. Certain acidophilic areas of hyaline necrosis widely scattered in the parenchymatous cells are termed "Councilman bodies." Superficial hemorrhages are often seen in the mucous membranes of the stomach, particularly in the pyloric end, and in the intestines. Although the spleen is approximately normal in size, there is usually degeneration of the malpighian corpuscles. Both the tubular epithelium of the kidneys and the cardiac muscle show involvement similar to that in the liver. The brain at times shows perivascular hemorrhages.

**Clinical Manifestations.** The majority of infections are so mild that they do not show the classic picture and are frequently missed.

The acute onset following the incubation period is similar, in the more severe cases, to a sharp attack of epidemic influenza except for lack of cough and evidences of upper respiratory tract infection. Headache, chills, backache, pains in the limbs and flushing of the face all appear suddenly and in a severe form, and photophobia and conjunctival injection are prominent. Initially, jaundice is absent or only slight. As a rule, during the first two or three days the temperature rises rapidly to 103° to 104° F. with an increasing pulse rate, and then diminishes relatively

more slowly than the pulse rate in what is frequently a temporary remission. During this period, albuminuria develops with pain and tenderness in the epigastrium, and there is vomiting without blood. The leukocyte count slowly decreases.

In the succeeding stage the temperature is again elevated, and the early signs and symptoms are replaced by prostration and depression; the face has a pale, cyanotic appearance, and there is a slowly increasing jaundice, which is rarely extreme. Hemorrhages into the skin and often into the gums usually appear at this time with epistaxis, a dry, brown tongue and a decreasing pulse rate to less than 50 per minute in spite of high fever (Faget's sign). Degenerative changes in the heart result in cardiac dilatation and a low blood pressure. The urine contains large amounts of albumin and casts. There is usually vomitus of a dark brown material, and the leukocyte count often drops to 3000 cells, from which it rises slowly as the patient recovers. In severe and often in fatal cases bile appears in the urine, or at times there is anuria followed by convulsions or coma.

If recovery occurs, improvement starts about the fifth or sixth day, and the temperature often is normal by about the eighth day. When convalescence begins, progress is continuous without complications. There is permanent immunity to the disease.

**Diagnosis.** There may be considerable confusion in diagnosis in the milder cases. Leptospirosis is particularly difficult to differentiate clinically. Infectious and serum hepatitis are usually far slower in development and subsidence. Somewhat more severe cases of yellow fever may initially be confused with influenza, malaria or dengue.

Such diagnostic difficulties can best be resolved by neutralization tests performed on mice with acute and convalescent serums, the latter being obtained about three weeks after the onset. Blood obtained from the patient during the first three days of disease and injected intracerebrally into susceptible mice will cause encephalitis in the mice if the yellow fever virus is present. The examination of acute and convalescent serums is more practical, since in the mouse-brain test, after further passage of the encephalitic mouse brain, a neutralization test must finally be carried out before the presence of the yellow fever virus can be confirmed.

**Prognosis.** It is probable that the over-all case fatality rate is not over 5 per cent, but

in any outbreak the fatality rate of recognized cases may be high, up to 50 per cent or more.

**Prophylaxis.** The strain of active yellow fever virus termed 17D, which has become avirulent after many passages on tissue cultures, may be used for vaccination of those likely to be exposed to the disease. Vaccines developed from this strain have been extremely effective in preventing yellow fever. They afford immunity within one week of injection which lasts for at least six years.

Urban communities should use methods to rid themselves of the *aegypti* mosquito by the districting and weekly inspection with a flashlight of all homes and their surroundings. The larvae may thus be found and eliminated. Netting should be used to prevent access of *Aedes aegypti* to the patient, and the room and house should be sprayed with an insecticide such as DDT.

**Treatment.** Specific therapy is lacking. Complete bed rest is essential to lessen the danger of cardiac failure, and sufficient fluids must be provided for the formation of urine. In order to prevent irritation of the gastric mucosa, solid food should be avoided. If vomiting is extensive, fluids should be administered parenterally in large amounts. Parenteral fluids should include glucose, saline and amino acid solutions, blood or plasma and the water-soluble vitamins. Because of diminution in prothrombin and fibrinogen, vitamin K should also be given and, if possible, plasma concentrates which contain the coagulating materials. Codeine may be used for vomiting. An ice cap should be kept at the head, and for excessively high temperatures the body should be sponged with cool water. Good oral hygiene is essential.

## LYMPHOGRANULOMA VENEREUM (LYMPHOGRANULOMA INGUINALE)

**Etiology.** Lymphogranuloma venereum is caused by a virus\* which is relatively large and stains with aniline dyes. Among the laboratory animals susceptible to this virus are mice, hamsters, rabbits, guinea pigs and monkeys. The virus is successfully grown on the chorio-allantoic membrane and in the yolk sac of the chick embryo. Antigen obtained from this source is used for skin tests and for complement fixation tests. As a result of infection, man develops circulating antibodies and skin sensitivity to the virus. The virus is closely related to those of meningo-pneumonitis of mice and of psittacosis and is one of the causes of atypical pneumonia.

The majority of children with lymphogranuloma venereum acquire the disease from nonsexual contact. The virus usually enters through an abrasion in the penis or the vulva or may penetrate the urethra, resulting in a mild urethritis.

**Clinical Manifestations.** Inguinal node enlargement is the most prominent manifestation of the disease and may be the first and only sign, since the primary lesion is rarely discovered in children. Cervical and axillary lymphadenopathy has been described following mouth and hand lesions. Rectal and anal strictures, common in adults, are infrequent in children. This is explained by the site of the primary lesion. The lymph drainage from the vulva, clitoris and urethra is to the inguinal nodes, and drainage from the vaginal mucosa, the site of most primary lesions in the adult female, is to the lymph nodes around the rectum.

The lymphadenopathy is chronic; the nodes frequently suppurate and give rise to multiple fistulas. Joint involvement has been observed, roentgenographically, in children. The joint space was slightly increased, and there was a slight, diffuse bony rarefaction. Erythema nodosum is an infrequent complication.

Parinaud's oculoglandular syndrome, a unilateral conjunctivitis followed by a chronic enlargement of the parotid and anterior cervical glands, may be caused by the virus of lymphogranuloma venereum as well as by a variety of other infectious agents.

**Diagnosis.** Lymphogranuloma venereum may be suspected, but the diagnosis cannot be established without the aid of laboratory

tests. These are a skin test (Frei) with inactivated virus and a complement fixation test. The Frei test is performed by injecting 0.1 cc. of the antigen (Lygranum) intradermally into the flexor surface of the forearm; a similar amount of control material is injected in the other arm. A positive test consists of a firm papule 5 mm. or more in diameter, which appears within forty-eight to seventy-two hours, with a negative or only slight reaction at the site of the control inoculation. The test usually becomes positive three to eight weeks from the time infection occurred and then may continue to be positive for many years. Transient positive reactions have been reported in the course of psittacosis and atypical pneumonias and in patients with syphilis.

**Treatment.** The drugs of choice are the tetracyclines. Penicillin and chloramphenicol are much less effective. Therapy should be maintained for ten to fourteen days.

## INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is a generalized infection whose only essential sign is, at some time in its course, an increase in the mononuclear elements of the blood. The disease occurs most frequently in the spring and fall, occasionally in outbreaks of fairly large proportions, although its communicability is usually low. It occurs most often in older children and young adults, although no age group or race is immune. The etiologic agent has not been identified, but is probably a virus. The disease has been transmitted from man to the monkey and the rabbit.

**Clinical Manifestations.** The incubation period is considered to be approximately eleven days. The onset may be insidious or acute. The most consistent clinical manifestations are generalized malaise, fever and sore throat. The last may appear early or late in the course of the disease. Fever is a fairly constant finding and may persist for several weeks; it is usually characterized by morning remissions. Enlargement of lymph nodes may occur early or late in the disease, but most frequently appears during the febrile phase. The posterior cervical nodes are usually the first to enlarge; any or all of the regional nodes can be involved. The salivary glands are rarely enlarged. The enlarged lymph nodes are usually nontender and rarely suppurate. The enlargement may disappear quickly or persist for weeks to months. The spleen is palpable in about 50 per cent of

\* This agent is classified in Bergey's Manual as a rickettsia.

cases, usually by the end of the first week of illness, and may remain enlarged for a long time.

Skin rashes occur in 9 to 18 per cent of cases and usually appear between the fourth and tenth days of the disease in the form of a discrete macular eruption (Fig. 157) which is most prominent over the trunk. They may assume a petechial, vesicular, morbilliform or scarlatiniform appearance. The hands, thighs, legs and feet are rarely involved.

Jaundice is evidence of hepatic involvement, but present evidence indicates that the liver is frequently involved without discernible jaundice. The possibility of confusing infectious mononucleosis with infectious hepatitis is especially likely in view of the lymphocytosis which frequently accompanies the latter disease.

Central nervous system manifestations consist in headache, stiffness of the neck, blurring of vision, mental confusion and, rarely, convulsions. The cerebrospinal fluid may be normal, or there may be an increase in mononuclear cells and in protein content.

Pericarditis with characteristic clinical manifestations and electrocardiographic changes may occur during the acute phase and prolong the convalescence.

**Diagnosis.** The laboratory aids are the changes in the monocytes in the peripheral blood and a positive heterophile antibody test.

The characteristic hematologic alteration is in the lymphocytes, which vary greatly in size and shape; they have been divided into three groups by Downey and McKinlay.

Type I cells are most common. Their nuclei are oval or lobulated and are usually eccentrically placed. The cytoplasm usually stains a deep blue, with an irregular, mottled appearance, except in the nuclear indentation, where it stains pink with fine carmine granules. Type II cells are somewhat larger, and their nuclei have more regular shapes and certain coarse, distinct chromatin strands. The cytoplasm is somewhat smoother, lighter staining and less mottled, with irregular strands of deep blue-staining material extending out from the nucleus to the periphery of the cell. Type III cells resemble lymphoblasts of lymphocytic leukemia; their nuclei tend to be regular in shape, but disproportionately large. The chromatin pattern is more delicate with one to three nucleoli occasionally present. The small amount of cytoplasm may be quite basophilic.

The total leukocyte count is usually elevated, but may be normal or low. The polymorphonuclear cells are often increased initially, but in the fully developed case a rela-

tive reduction in granulocytes is characteristic. The rise in lymphocytes usually begins on the fourth or fifth day, and by the seventh or tenth day these cells constitute 60 to 90 per cent of the total leukocytes. In rare instances thrombocytopenia with purpura and prolonged bleeding time, agranulocytosis and anemia may be encountered.

The heterophile antibody test of Paul and Bunnell usually becomes positive (60 per cent or more of cases) during the first week of the disease or shortly thereafter and may remain positive for varying periods of time. Since the titer of agglutinins may reach a peak quickly and subside rapidly, a positive test may be easily missed. Falsely positive heterophile antibody tests may occur in patients who have received horse serum and rarely in other acute infections. The Barrett modification of the Paul-Bunnell test makes the heterophile antibody reaction even more specific. There are three types of heterophile antibodies in human serums which agglutinate sheep red blood cells: (1) The type found in human serums after horse serum injection is absorbed by either ox erythrocytes or guinea pig kidney. (2) The type found in infectious mononucleosis is absorbed by ox erythrocytes, but not by guinea pig kidney. (3) The type found in normal serums is absorbed by neither. Thus the spe-

FIG. 157. Morbilliform rash in mononucleosis.

FIG. 158. Peripheral blood smear from a patient with infectious mononucleosis. In the lower left corner is a normal monocyte; the 2 lymphocytes are Downey type I cells, commonly encountered in this disease. The nucleus, which often is eccentrically placed, is lobulated with the chromatin arranged in coarse clumps. The cytoplasm stains a deep blue; there is a characteristic lighter perinuclear area most pronounced in the hilus of the nucleus. (Blackfan and Diamond: *Atlas of Blood in Children*. New York, Commonwealth Fund.)

cific antibody can be titrated. By this test, titers of 1:40 or higher are considered diagnostic. By the usual technique 1:64 or higher is considered significant.

Patients with infectious mononucleosis may show a falsely positive complement fixation (Wassermann and/or Kahn) test for syphilis, which usually appears during the second week of the disease and becomes negative within two weeks, though it may persist longer. Patients in whom a rash develops appear more likely to have a falsely positive serology than do those who do not have an eruption.

**Prognosis.** The prognosis is good even in the rare cases when central nervous system manifestations are marked. Weakness and easy fatigability may persist for a long time. There are no sequels of significance with the exception of rare cases of chronic hepatitis. Fatalities have occurred in young adults from rupture of the enlarged spleen.

**Treatment.** There is no specific therapy. Bacterial complications are not common, and should be treated appropriately. The convalescent period is likely to be prolonged, though less in children than in adults; an initial period of fourteen to twenty days in bed may be indicated in the average case.

Subsequent increases in activity should be gradual, being based on evidences of fatigue and the patient's temperature. A generous intake of protein and vitamins is indicated.

#### ACUTE INFECTIOUS LYMPHOCYTOSIS

This infection, originally thought to be a variant of infectious mononucleosis, was described and named by Carl Smith in 1941. The outstanding characteristic is the increase in the total number of lymphocytes in the peripheral blood and in the bone marrow which persists over relatively long periods of time. Initially it was thought that there were few or no clinical manifestations. Subsequent observations, however, have disclosed a variety of symptoms and signs, such as fever, nasopharyngitis, abdominal complaints, skin rashes, and mild meningoencephalitic manifestations.

**Etiology.** Bacteriologic and viral studies have not disclosed a causative agent.

**Epidemiology.** On the basis of institutional epidemics and the occurrence of multiple cases in families, the disease is considered to be infectious. The incubation period is estimated to be twelve to twenty-one days. Most cases have been in children less than ten years of age. The disease has been observed in the Americas and in Europe. Nothing is known about the development of immunity.

**Pathology.** Microscopic examination of lymph nodes has shown degeneration of the lymph follicles and proliferation of the reticuloendothelium of the sinuses.

**Clinical Manifestations.** In the majority of the cases observed there are no symptoms and no abnormal physical findings, or they are so mild that they escape attention. In a few instances there are fever and variable, but short-lived, complaints at the onset. These complaints include upper respiratory infections with throat manifestations predominant, vomiting, irritability, abdominal pain and diarrhea and, infrequently, signs referable to the central nervous system. The abdominal signs may infrequently be severe enough to suggest an acute surgical emergency. Several instances are recorded in which the clinical pattern was that of a meningoencephalitis, and one instance in which there was paralysis, similar to that occurring in poliomyelitis, and a slight increase in the cerebrospinal fluid cell count. A mild, generalized morbilliform rash of several days' duration, similar to that in infectious mononucleosis, has been observed. Slight enlargement of the lymph nodes or spleen has been observed, but is apparently infrequent.

**Laboratory Data.** The only characteristic finding is the high white blood cell count, which may range from 22,500 to 120,000 per cubic millimeter, the lymphocytes varying from 62 to 97 per cent. The lymphocytes are normal in appearance and are mainly of the small variety. There may be a slight eosinophilia. There is no abnormality of the erythrocytes or platelets.

The heterophile agglutination test is negative. The bone marrow contains an increased number of normal or postmature lymphocytes; otherwise it is not abnormal. The changes apparently persist longer in the bone marrow than in the peripheral blood.

**Diagnosis.** The disease must be differentiated from infectious mononucleosis, acute leukemia, infections associated with a lymphocytosis, principally pertussis, and rarely

from acute abdominal conditions and meningoencephalitis of other causes.

*Infectious mononucleosis* can be distinguished only by a positive heterophile agglutination test and by demonstration in the peripheral blood of the abnormal lymphocytes typical of the disease. The clinical pattern of infectious mononucleosis, however, is likely to be much more severe, being characterized by fever, malaise, sore throat, enlargement of lymph nodes and often of the spleen, and occasionally by a rash and jaundice.

*Acute lymphatic leukemia* may cause some difficulty initially, but the presence of abnormal lymphoblasts in both leukemic and aleukemic phases of leukemia, diminution of erythrocytes and platelets, leukemic invasion of the bone marrow, and the progressively downward course combine to make a clear differentiation.

Extremely high lymphocytic counts are occasionally observed in *pertussis*, but usually with the more severe cases, so that the characteristic clinical manifestations are usually adequate to determine the diagnosis.

*Acute abdominal conditions* which would require operation apparently can occasionally be simulated. In such cases the high lymphocytic count should speak for a period of watchful waiting; in acute infectious lymphocytosis the abdominal complaints can be expected to disappear.

The differentiation of a *meningoencephalitis* of other etiology presents greater difficulties. Exact diagnosis of the various viral encephalitides can be established with certainty only by laboratory means (p. 384). The possibility of confusion with poliomyelitis is suggested by the report of one case.

**Course and Prognosis.** In the few instances in which there have been abnormal symptoms they were only of a few days' duration. Otherwise the course can be measured only by laboratory data. The lymphocytosis persists for weeks, and was observed for seven months in one case. The disease is apparently exceedingly benign, no sequels having been recognized or deaths recorded.

**Treatment.** Except for symptoms present at the onset, no therapy is indicated.

## CAT-SCRATCH FEVER

(BENIGN INOCULATION LYMPHORETICULOSIS; CAT-CLAW DISEASE; CAT-BITE FEVER)

Cat-scratch fever is now recognized as a relatively common disease of man, and the role of the domestic cat in its transmission seems to have been established. Observed as early as 1930 in France and in the United States, the disease as an entity has been brought to general attention comparatively recently.

**Etiology.** The etiologic agent, though not identified, is thought to be a virus of the psittacosis-lymphogranuloma venereum group. Attempts to isolate the agent from suppurative lymph node material have been unsuccessful, but transfer of the disease to monkeys and to human volunteers has been accomplished. Stained sections of primary skin lesions and involved lymph nodes from both man and monkeys show large numbers of intracellular and extracellular granule-like bodies similar to those of psittacosis.

**Epidemiology.** It appears probable that distribution is worldwide. To date cases have been reported from France, Great Britain, Canada, Australia, the United States, South America, Switzerland and India. On the basis of similarity in the type of elementary body, a possible relation between the etiologic agent of cat-scratch fever and that of feline pneumonitis has been suggested. The infectious agent of the latter is antigenically related to the psittacosis-lymphogranuloma venereum viruses. It can be isolated readily, and passage is established in mice by intranasal inoculation. A similar transfer of pus from infected nodes of cat-scratch disease has not resulted in disease in mice. Cats which transfer the agent to human subjects show no evidence of illness and have no reaction to the intradermal injection of the antigen. Their role is considered to be simply that of a vector.

**Pathology.** Examination of involved lymph nodes has revealed only nonspecific morphologic changes, classified into distinct phases: (1) an "elementary" phase of simple hyperplasia; (2) an "accentuated" phase in which, in addition to hyperplasia, areas of early cellular necrosis stain as acidophilic masses; and (3) the "ultimate" stage in which the lymph node architecture is displaced by multiple areas with central necrosis and by circumscribed foci of epithelioid cells and scattered giant cells of the Langhans type (pseudotubercles). The final phase corre-

sponds to the clinical stage when the enlarged node becomes fluctuant.

**Clinical Manifestations.** Cat-scratch fever is a nonfatal systemic illness characterized by malaise, headache, low grade fever and lymphadenitis. Though as a rule the patient does not appear acutely or chronically ill, the size of the involved lymph node, or nodes, is often striking. In most instances the history will reveal association with cats, with or without the recollection of a specific abrasion. The incubation period varies from ten to thirty days. In one volunteer subject regional adenopathy began in eight days and progressed to fluctuation in about twenty. At the height of the lymph node response a skin papule appeared at the site of the primary intradermal inoculation and persisted for several days.

The foregoing sequence appears to be characteristic of the natural infection. At the time medical advice is sought there is usually an exacerbation of redness and swelling at the site where a primary lesion is in the process of healing. This lesion tends to heal slowly and may resemble an insect bite, a small furuncle or a scab following simple trauma. The nodes involved are those which drain the area where the initial lesion occurred, commonly the epitrochlear, axillary, submandibular, cervical or inguinal ones. The skin overlying enlarged nodes may show some redness, but more often is normal in appearance. Involved lymph nodes may be hard or soft and vary in diameter from 1 to 5 cm.; on aspiration a purulent fluid may be obtained, from which no bacteria can be cultured.

Unusual clinical manifestations have included cervical adenitis thought to result from inhalation or aspiration of the etiologic agent, transient pulmonary infiltration associated with otherwise typical cat-scratch fever, and an oculoglandular form of the disease with conjunctivitis and enlargement of preauricular and cervical nodes. Purpura and skin rashes of the erythema multiforme and nodosum types have been observed. An osteolytic lesion, which healed spontaneously, has also been observed.

Central nervous system involvement, classified as encephalitis, encephalomyelitis and myelitis and radiculitis, may accompany or follow the acute phase. Onset of neurologic symptoms is usually abrupt with high fever. The cerebrospinal fluid usually has a moderate increase in both lymphocytes and in protein.

**Laboratory Data.** There are no conclusive

data; there may be a moderate leukocytosis with a slight shift to the left.

**Skin Test.** Patients with cat-scratch fever have a positive skin reaction from the intradermal injection of the antigen prepared by the Frei procedure from an involved lymph node of a known case. The following procedure is a convenient method for preparing skin test antigen.

A suppurative node is aspirated under aseptic conditions, and the material is injected directly into a sterile puncture-type vial containing 2 to 3 cc. of isotonic saline solution. The vial is shaken vigorously in order to ensure dispersion, and additional saline solution to give an approximate 1:5 dilution is immediately injected into the vial. No anticoagulant is necessary if dilution is accomplished quickly. On each of two successive days the diluted material is heated for one hour at 56° to 60° C. If this potentially antigenic material proves by routine culture to be sterile, it should be tested intradermally in volunteers to rule out nonspecific skin reactions. Since antigens of this type carry the possible risk of exposure to hepatitis, there is need for caution.

The skin test is performed by injecting intradermally 0.1 cc. of the antigen, the site being observed at intervals of forty-eight and seventy-two hours. A typical positive reaction consists of an indurated, raised, erythematous wheal 5 mm. or more in diameter which is surrounded by a zone of erythema 30 to 40 mm. in diameter. The erythema may disappear in one to two days, but as a rule the wheal can be recognized for four or five days more. A positive skin test may be ob-

tained for years following cat-scratch infection. No regional adenopathy is associated with a positive reaction to the intradermal injection of the antigen.

**Differential Diagnosis.** Cat-scratch fever is most commonly confused with simple pyogenic adenitis, but must also be differentiated from tuberculous adenitis, tularemia, rat-bite fever, Hodgkin's disease, lymphoma, fungus infections and lymphogranuloma venereum.

**Prognosis.** The prognosis in cat-scratch fever is uniformly good. The enlarged nodes regress spontaneously in one to three months after reaching their peak. In some instances fibrosis may result in persistent enlargement.

**Prevention.** At present, detection of cats carrying the infective agent is not possible, since they are apparently not ill and do not have a positive skin reaction to the antigen. Thus no control measures are apparent other than avoidance of contact with cats, and it does not seem likely that the cat is to be displaced as a household pet. Other means of transfer include abrasions by thorns and wood splinters and by fragments of bone in meat handlers. The obvious question, in such instances, is whether the persons involved had subsequent contact with cats.

**Treatment.** No therapeutic measures are known to be of benefit. Although in a few instances treatment with one of the broad-spectrum antibiotics was thought to shorten the course of the disease, the evidence is not conclusive. Occasionally drainage by aspira-

FIG. 159. Cat-scratch fever: primary skin lesion with associated cervical lymphadenitis. (Photograph courtesy of C. W. Daeschner.)

tion will hasten resolution of fluctuant nodes; the procedure does carry the risk of a draining sinus, but this usually heals with minimal scarring.

## CYTOMEGALIC INCLUSION DISEASE

Generalized cytomegalic inclusion disease is a rare systemic disease involving predominantly infants, and characterized by the presence of intranuclear and intracytoplasmic inclusion bodies in the enlarged cells of many viscera. The virus responsible for the disease has been isolated from salivary glands, liver, urine and from the aqueous humor of affected infants; a similar virus has been isolated from adenoid tissue of presumably healthy children.

The inclusion bodies are usually found in epithelial cells, but mesenchymal cells may

also be involved. Inclusion-bearing cells have been demonstrated in almost all organs of the body at postmortem examination. The tissue adjoining the involved cells may reveal no significant inflammatory response. In some instances, however, there is an associated infiltrate of lymphocytes or, less frequently, focal areas of necrosis or fibrosis. Excessive extramedullary hematopoiesis may be present, especially in the spleen and liver of infants dying during the neonatal period. The intranuclear inclusion body may occupy most of the enlarged nucleus of the affected cell, although characteristically it is separated from the nuclear membrane by a clear halo. Multiple intracytoplasmic inclusion bodies may be present, but are less constant than the intranuclear ones.

Serologic studies, which are still inadequate for diagnostic purposes, indicate that the virus responsible for the disease is widespread. Moreover, the characteristic inclusion bodies have been observed as incidental findings in the salivary glands in 10 to 32 per cent of fetuses and infants dying of a variety of causes; such a finding does not warrant the diagnosis of generalized cytomegalic inclusion disease. Similar inclusion bodies, disseminated in a variety of sites, have been encountered less frequently in infants, children or even in adults dying with debilitating diseases, e.g., fibrocystic disease of the pancreas and pertussis; the significance in such instances is not clear. It seems possible, however, that a latent viral infection may have become activated because of loss of resistance on the part of the host. Although such patients might properly be regarded as having generalized cytomegalic inclusion disease, it apparently represents only an intercurrent incident and not the primary cause of their illness.

The most constant clinical pattern associated with generalized cytomegalic inclusion disease occurs during the neonatal period. The infants are often below average birth weight and exhibit manifestations at the time of delivery or in the early neonatal period; rarely manifestations may not be apparent for several weeks. The manifestations are usually related to the hematopoietic system, liver and central nervous system, although any system may be involved. Hepatomegaly, splenomegaly, icterus, anemia, thrombocytopenia, purpura and cerebral calcification are among the more common clinical manifestations. The cerebral calcification is classically para-

ventricular in location and may be associated with microcephaly or hydrocephalus. Chorioretinitis is occasionally present, and the clinical pattern may thus be indistinguishable from that of congenital toxoplasmosis.

The *differential diagnosis* in the neonatal period includes erythroblastosis fetalis, sepsis, toxoplasmosis, congenital syphilis and such rarer diseases as generalized herpes simplex, congenital hemolytic icterus and congenital leukemia. These can usually be excluded by appropriate laboratory studies. A definite diagnosis can be established by demonstration of the typical inclusion-bearing cells in smears of the urinary sediment or less frequently in gastric washings or possibly in bronchial secretions or cerebrospinal fluid; inclusion bodies may still be demonstrable in specimens of urine obtained from infants several months of age.

In infants whose first manifestations of the disease occur in the postnatal period the clinical pattern is somewhat more varied. Evidence of interstitial pneumonitis and diarrhea are apt to be prominent symptoms. The inclusion-bearing cells may be limited to the lungs or intestinal tract or may be widely disseminated through the viscera.

Information about the natural history of the disease is still inadequate, since until 1952 the diagnosis had been made only at postmortem examination. However, the evidence indicates that the disease is a serious but not invariably a fatal one. Permanent cerebral damage, although often present in patients who survive, may be of varying degrees of severity, and rarely no permanent sequels are apparent. The prognosis for future pregnancies is apparently good; only one instance is known of infection in two infants of separate pregnancies of a given mother.

## INFECTIOUS NEURONITIS

(INFECTIOUS POLYNEURITIS, GUILLAIN-BARRÉ SYNDROME)

Infectious neuronitis is a disease of unknown etiology characterized by a slowly progressive ascending paralysis. The disease frequently follows an acute infection and is thought by many to be the toxic effect of the original infection. Others feel that infectious neuronitis is caused by a virus; however, animal experiments have thus far failed to demonstrate such an agent. It appears likely that the clinical picture of infectious neuronitis may be caused by several different agents. The development of the Guillain-Barré syndrome has been noted in association with diphtheria.

In the usual case, signs of a peripheral neuritis develop symmetrically in the lower extremities several days after an upper respiratory infection. The muscles become tender, and deep tendon reflexes are abolished or greatly diminished; cutaneous reflexes are usually maintained. Sensory loss may be marked, but in most cases is slight. Cramping pains and paresthesias may occur. The muscles become paralyzed, and the paralysis moves upward, often involving the abdominal and thoracic muscles. Involvement of the cranial nerves is uncommon, except of the facial nerves, which is usually bilateral. Muscular atrophy is not marked in this disease, and recovery is usually complete, especially in children. The course of the disease tends to be prolonged with a gradual return of function to the paralyzed muscles. Fatalities are uncommon, but may occur as a result of respiratory paralysis.

Fever is not conspicuous in infectious neuronitis and may be absent. A diagnostic feature of importance is an increase in the protein of the cerebrospinal fluid with little or no increase in the cell count. The symmetry of paralysis and the increase in cerebrospinal fluid protein serve to distinguish this disease from poliomyelitis.

Pathologic changes are found in the peripheral nerves and nerve roots, and consist in degeneration in the myelin and in the axis cylinders. There may or may not be evidences of inflammatory reaction. No characteristic central nervous system changes are found. Visceral lesions have also been reported which consist in focal necroses in liver, kidneys and adrenals with round cell infiltration.

*Treatment* is symptomatic; no specific therapy is available. Acceleration of recovery has been reported when therapy with corti-

cotropin or cortisone was initiated early in the course of the disease.

SYDNEY S. GELLIS

## INFECTIONS BY ENTERIC VIRUSES (ENTEROVIRUSES)

Viruses which inhabit the alimentary tract and appear to be natural parasites of man include the poliomyelitis, Coxsackie and ECHO (enteric cytopathogenic human orphan) viruses. These agents, referred to as the enteroviruses, have many properties in common, including small size, relative durability as exemplified by resistance to ether, maximal prevalence in warm weather (summer season in temperate zones) and other similarities of epidemiologic pattern. Many of these viruses produce disease in man, and all induce recognizable infection in one or more of various experimental hosts, including primates, rodents, and cells in tissue culture.

Table 75. Association of Enteroviruses with Human Disease\*

<i>Enteroviruses</i>	<i>Associated Disease</i>
Poliovirus.....	Paralysis (complete to slight muscle weakness) Aseptic meningitis Undifferentiated febrile illness, particularly during the summer
Coxsackie viruses, group A.....	Herpangina Undifferentiated febrile illness, particularly during the summer Aseptic meningitis (types A-7, A-9)
Coxsackie viruses, group B.....	Aseptic meningitis Pleurodynia Undifferentiated febrile illness with pharyngitis Myocarditis or encephalomyocarditis during neonatal period and early childhood Mild paralysis (?)
ECHO viruses...	Aseptic meningitis (types 2, 3, 4, 5, 6, 9, 14, 16) Summer rash (types 4, 9, 16) Summer febrile illness Mild paralysis (?) (type 6) Summer diarrhea of infants and children (type 18 and others)

The associations of enteroviruses with human diseases as currently recognized are indicated in Table 75.

Poliomyelitis is discussed on page 531.

## COXSACKIE VIRUS INFECTIONS

**Etiology.** Coxsackie viruses have in common the capacity to induce fatal infections, frequently with paralysis, in suckling mice and hamsters. The route of inoculation, the strain of virus and the size of the dose, as well as the age of the host, influence the manifestations of infection. Dalldorf has classified these agents into two groups based on the features of disease induced in suckling mice. Group A viruses characteristically cause extensive destruction of skeletal muscle without lesions elsewhere. Group B viruses cause varying degrees of focal damage to skeletal muscle as well as myocarditis, fat necrosis, pancreatitis, encephalomyelitis and, less regularly, lesions in other organs. Group B viruses also induce a form of pancreatitis in mature mice in which the islets of Langerhans are spared and the acinar tissue first becomes necrotic and then is replaced by fat.

Nineteen Coxsackie viruses of group A (designated A-1 to A-19) and five of group B (designated B-1 to B-5) have been identified to date. Each of these agents is antigenically distinct and can be identified and differentiated by neutralization and complement fixation tests with specific immune animal serums, as well as by determinations of active immunity in mice or chimpanzees. Circulating antibodies can usually be detected in the human or animal host within two weeks of infection or the onset of symptoms.

A-7 and A-14 viruses induce poliomyelitis-like lesions in monkeys. Strains of virus recovered from children with paralytic disease and thought by Russian workers to represent a fourth type of poliovirus have been identified as Coxsackie virus A-7. Only two types, A-2 and A-8, have been found to multiply in chick embryos; A-4 has been grown in chick cells. Strains of all five group B and

several group A viruses grow and produce cytopathic changes in tissue cultures of trypsinized monkey kidney cells.

Coxsackie viruses are relatively small with diameters in the range of 25 to 30 millimicrons. An A-10 strain has been purified and crystallized.

Coxsackie viruses are unusually stable. Viral activity is maintained at room temperature for many days and can be preserved for a long time if infected tissues are stored in glycerin or in a frozen state. In aqueous suspensions activity disappears after exposure to a temperature of 60° C. for thirty minutes. When these viruses are suspended in milk or ice cream, higher temperatures are required for their inactivation. Like poliomyelitis viruses, these agents retain their activity through a wide range of pH (2.3 to 9.4 for one day and 4.0 to 8.0 for a week). They are not inactivated by ether, 70 per cent ethyl alcohol, 5 per cent Lysol, 1 per cent Roccal, or antibiotics, but are inactivated rapidly by tenth-normal hydrochloric acid and 0.3 per cent formaldehyde.

**Epidemiology.** Coxsackie viruses have been encountered throughout the world. Like poliomyelitis and ECHO viruses, these agents have been recovered most commonly from human feces and pharyngeal swabbings, and also from sewage and flies. Strains of all the group B types and A-9 virus have been recovered from the cerebrospinal fluid of patients with aseptic meningitis. Recovery of a Coxsackie virus from human blood, tissue or other sources has been relatively uncommon. No natural reservoir of infection other than man has been found, although flies and possibly cockroaches are able to transport these agents.

Coxsackie viruses have been recovered mainly in the summer and fall, and more frequently from children than from adults. Rates of infection may be higher in persons with poor living conditions. Some of these viruses may cause epidemics of human disease, usually in the summer and fall, but at unpredictable intervals and locations. Any one of six different group A viruses may cause herpangina. Group B viruses, especially B-1 and B-3, have been responsible for widely separated outbreaks of the syndrome pleurodynia. All of group B and A-7 and A-9 viruses can produce meningoencephalitis in man, the group B agents sometimes in association with epidemic myalgia. The infrequent production of paralytic disease by one of these agents has

been demonstrated most convincingly with A-7 virus. Group B viruses may cause myocarditis, which in newborn infants is highly fatal.

Successive infections with strains of a single type of Coxsackie virus have not been reported; immunity appears to be type specific and relatively lasting. Communicability of infection by Coxsackie viruses is similar to that in poliomyelitis.

**Pathology.** Relatively few observations have been made of pathologic changes in man. Myocarditis, encephalitis, hepatitis and, in one instance, inflammatory changes in the spinal cord have been observed in newborn infants with fatal disease attributed to a group B virus. In a few instances myositis and degenerative changes have been observed in biopsies of skeletal muscle.

**Diagnosis.** Diagnosis of infection by a Coxsackie virus is suggested by clinical and epidemiologic findings and confirmed by recovery of virus from feces, oropharyngeal swabbings, cerebrospinal fluid or, rarely, blood, and by demonstration of a related increase of specific neutralizing antibodies in serial specimens of serum obtained during the acute and convalescent phases of illness. Since infection by one of these viruses stimulates complement-fixing antibodies to heterologous strains, determinations by this technique are of limited diagnostic value.

**Prognosis.** Diseases attributed to infection by a Coxsackie virus appear in most instances to be relatively benign, self-limited and usually uncomplicated. Fatalities have occurred in newborn infants with myocarditis and encephalomyelitis and much less often in children with central nervous system involvement.

**Treatment.** No therapeutic measure is known which affects the course of infection by an enterovirus. Treatment is entirely supportive and symptomatic.

**Prophylaxis.** Effective measures to control infection by Coxsackie or ECHO viruses are not available. Attempts to limit the spread of infection within the home or an institution should be based on recognition of the fact that these agents may be distributed directly or indirectly by the oropharyngeal secretions or feces of infected persons, many of whom remain undetected. Since enteroviruses are unusually stable at ordinary temperatures and resistant to solutions commonly used as antiseptics, decontamination of objects which cannot be boiled or autoclaved, as, for example,

rectal thermometers, can be accomplished only by immersion in tenth-normal hydrochloric acid or 0.3 per cent formaldehyde.

## CLINICAL DISORDERS

### HERPANGINA

This acute febrile disease, first described by Zahorsky, was shown by Huebner and his associates to be caused by any one of six group A viruses (types A-2, A-4, A-5, A-6, A-8 and A-10). It occurs during the warm months, affects mainly children, and is characterized by distinctive faucial lesions.

After an incubation period of two to four days the illness is usually initiated by an abrupt elevation of temperature to as high as 105° F. Anorexia and dysphagia are common, and most patients over two years of age complain of sore throat. Headache and abdominal pain are encountered less often. Infrequently convulsions occur with the fever. The pharynx is usually hyperemic. The characteristic discrete lesions appear initially as white or grayish vesicles, later as shallow ulcers 1 to 5 mm. in diameter, each surrounded by a red areola. They range from one to about fifteen in number and are commonly located on the anterior pillars of the fauces, less frequently on the palate, uvula or tongue, but not characteristically on the posterior pharyngeal, gingival or buccal mucosa. These lesions are not invariably present, however. Genital ulceration attributed to infection by A-10 virus has been described in a seven-year-old-girl with herpangina. Acute parotitis complicating herpangina has also been reported. Rhinitis, cough, otitis media, sinusitis, diarrhea, generalized myalgia and meningeal irritation are not typical features of herpangina. The illness generally follows an uncomplicated course to recovery. Fever may last one to four days, and the ulcers heal within a week. The white blood cell count is usually normal or only slightly elevated.

A *diagnosis* of herpangina is suggested by the occurrence of an acute self-limited disease prevalent in the community in spring, summer or fall and characterized by typical faucial lesions which, unlike those of herpetic or aphthous stomatitis, do not occur on the gingival or buccal mucous membranes. Infection by herpes simplex virus, unlike herpangina, is usually not epidemic and causes lesions on the skin and at mucocutaneous borders. Vesicles and ulcers similar to those of herpangina are occasionally seen in ECHO viral infections. Follicular tonsillitis due to

the hemolytic Streptococcus and the pseudomembrane of diphtheria do not resemble herpangina and can be correctly identified by culture. The oral lesions of acute exanthematous diseases, leukemia and infectious mononucleosis, as well as those seen in various deficiency states and following intoxication by heavy metals, are usually readily differentiated.

### PLEURODYNIA

(EPIDEMIC MYALGIA, DEVIL'S GRIPPE, BORNHOLM DISEASE)

The disease apparently first recognized by Finsen in 1856 in Iceland is widely distributed throughout the world. It is evident that group B Coxsackie viruses, especially B-1 and B-3, can induce pleurodynia. This relationship, first suggested by Curnen and co-workers, has been established by Weller and others. Outbreaks usually occur in the summer and fall. The true rate of occurrence is not known; in Denmark, where this disease is reportable, the incidence closely parallels that of acute poliomyelitis and of typhoid fever.

The incubation period is usually two to four days. The illness begins suddenly with fever, headache and pain, commonly located in the muscles of the lower chest or upper abdomen. Characteristic sharp or stabbing pain which may be extreme is accentuated by respirations and may be present on one or both sides. Sometimes pain is localized in the lower abdomen and may simulate an acute surgical condition. Superficial tenderness and palpable swelling of muscles in affected areas may be detected. The muscles of the extremities are rarely involved. Although pleurisy may be suggested, auscultation and roentgenologic examination of the chest seldom reveal abnormalities. Splenomegaly is infrequent. The white blood cell count is not unusual.

The fever and pain subside within two or three days, but in about a fourth of the cases they recur on one or more occasions after asymptomatic intervals of two or three days. Often several members of a family are affected with somewhat different manifestations and degrees of severity. Involvement of the central nervous system may be evidenced by convulsions, encephalitic manifestations or pleocytosis of the cerebrospinal fluid. Except for occasional meningeal involvement and orchitis in mature males, complications are unusual, and the disease terminates spontaneously in recovery.

Pleurodynia must be differentiated from other causes of thoracic pain, particularly pneumonia and pleurisy, and from other causes of abdominal pain, including acute gastroenteritis, appendicitis, peptic ulcer and disease of the gallbladder. Whether a group B Cocksackie virus can cause pancreatitis in man as in mice has not been determined. The superficial quality of the pain, the absence of deep abdominal or rectal tenderness, the relatively normal leukocyte count and the absence of abnormal roentgenologic findings should aid in the recognition of infection by a Cocksackie virus. The diagnosis is favored when other typical cases are occurring in a local epidemic; it can be confirmed by recovery of the virus and by demonstration of a type-specific antibody response.

#### MYOCARDITIS IN THE NEWBORN INFANT

Recent evidence from widely separate sources indicates that group B Cocksackie viruses may induce intrauterine or neonatal infection manifest in newborn infants by acute myocarditis. The onset is sudden, most often within the first ten days of life and sometimes shortly after a brief episode of diarrhea and anorexia. Tachycardia, dyspnea and cyanosis may appear early, and lethargy, grayish pallor and mild jaundice are typical manifestations. The temperature may be depressed or elevated. The heart, liver and sometimes the spleen are enlarged. Electrocardiographic changes are characteristic of myocarditis. The cerebrospinal fluid may be xanthochromic, and the leukocytes and protein may be increased.

The clinical course may be rapidly fatal or progress to complete recovery. In fatal cases virus has been recovered from the brain and spinal cord as well as from the myocardium. Recently myocarditis and pericarditis have also been observed as features of infection by group B Cocksackie viruses among older children and adults.

#### ASEPTIC MENINGITIS

Cocksackie viruses of group B now appear to be responsible for much of the aseptic meningitis or so-called nonparalytic poliomyelitis during the summer and fall months. Strains of all the group B types 1 to 5 and A-9 virus have been recovered from the cerebrospinal fluid of patients during the acute illness.

The clinical picture of aseptic meningitis caused by a Cocksackie virus is not distinctive for the various strains. The onset may be sudden or gradual; in approximately half of

the instances it is initiated by a prodromal phase. In one patient viremia with a B-2 strain was demonstrated five days before the appearance of meningeal signs. Anorexia, malaise, fever, nausea and abdominal pain are frequent early complaints. The temperature may be elevated to 104° F. or so. Ultimately headache, drowsiness, vomiting and discomfort or stiffness of the neck or back may appear, occasionally associated with focal or generalized myalgia. Physical examination may reveal hyperemia of the pharynx and some degree of resistance to flexion of the neck and back. Persistent muscular stiffness or weakness is usually equivocal or lacking. The reflexes remain physiologic.

The white blood cell count is normal or only slightly elevated. The cells of the cerebrospinal fluid are increased, but usually not in excess of 500 per cubic millimeter, except in patients with B-5 infection, when counts may be as high as 2000. The cells are predominantly lymphocytes, but initially the percentage of polymorphonuclear cells varies from 10 to 50 per cent; protein and sugar levels are usually normal.

The course is characteristically uncomplicated and terminates in complete recovery; especially in adult patients, fatigue and irritability may persist for several months. Paralytic involvement is rare.

Differentiation of Cocksackie viral meningitis from other infections of the aseptic meningitis syndrome (p. 544) may be suggested by clinical and epidemiologic data. The diagnosis can usually be established by appropriate serologic tests and, in some instances, by recovery and identification of the responsible agent, especially from the cerebrospinal fluid. Differentiation from nonparalytic 'poliomyelitis is not possible on the basis of clinical findings; persistence of muscle spasm, however, is more suggestive of poliomyelitis.

#### ECHO VIRUS INFECTIONS

**Etiology.** ECHO viruses, some of which have been referred to earlier as "orphan" or "human enteric" viruses, now comprise nineteen different antigenic types and have in common a number of properties. They are cytopathogenic for human or monkey cells in tissue cultures. They are not neutralized by antisera for the three types of polioviruses or by antisera for Cocksackie viruses which induce cytopathogenic changes in tissue culture. In general they do not cause disease in newborn mice, although types 9 and

10 after passage in tissue culture appear to be exceptions in this respect and cause lesions in suckling mice resembling those produced by Coxsackie A and B viruses, respectively. Some of the ECHO viruses (types 1, 2, 3, 4, 6, 10 and 13) produce neuronal lesions in monkeys. After immunization of monkeys and rabbits with ECHO viruses higher titers of neutralizing antibody are found in serums from the former than from the latter; this may be another reflection of viral multiplication in monkeys. Clinically inapparent infections associated with excretion of virus and homologous antibody response have been demonstrated in chimpanzees.

ECHO viruses are not related to other viruses recovered from the alimentary tract of man by means of tissue culture. Neutralizing antibodies to ECHO viruses are found in gamma globulin and in human serum. Although these agents have been classified to date into nineteen different types, considerable variation has been recognized between individual strains of certain types, especially types 4 and 6. Some evidence suggests that types 1 and 13 are related and may be identical. Kidney cells of different monkey species vary in their susceptibility to ECHO viruses. Separation of the ECHO viruses into two groups based on the kind of plaque formation and the capacity to propagate in cultures of cells from different species of monkeys has been suggested by Melnick.

ECHO viruses are relatively small, being about the same size as Coxsackie viruses and polioviruses with the exception of type 10, which is considerably larger (approximately 75 millimicrons in diameter) and differs in additional features from other ECHO viruses. As far as has been determined, ECHO viruses appear to resemble poliomyelitis and Coxsackie viruses in respect to other physical properties, including thermal stability and resistance to inactivation by ether, common antiseptics and other antimicrobial agents.

**Epidemiology.** ECHO viruses have been encountered in many parts of the world, characteristically in the summer and fall seasons, more frequently in children than in adults, and have been recovered more readily from feces than from oropharyngeal swabbings. Some ECHO viruses are commonly present in the human intestinal tract and are found there most frequently among young children from families of relatively low socioeconomic status. A number of ECHO viruses, particularly representatives of types 4, 6 and 9, have been associated with epidemics of

aseptic meningitis in various parts of North America and Europe. Many patients with aseptic meningitis attributable to ECHO virus type 9 exhibit a transitory exanthem. A rubella-like rash and meningeal involvement have been observed during outbreaks with ECHO type 16 virus, but the two manifestations have not been noted in the same patient. In outbreaks of aseptic meningitis attributable to ECHO virus, types 4, 6 and 9, associated cases of mild or inapparent infection were recognized, and presumably many others were undetected. The high attack rate and morbidity in families indicated that infection spread rapidly, probably from person to person. In communicability of infection ECHO viruses are similar to other enteroviruses. Although the ECHO viruses appear to be natural parasites of man, biologically similar enteric viruses have been found in monkeys, cattle and swine.

**Pathology.** Almost no information is available concerning the pathologic changes caused by ECHO viruses. A virus, subsequently identified as ECHO virus type 2, was recovered by Steigman from the spinal cord of a child who died of a disease which clinically and pathologically resembled bulbospinal poliomyelitis.

**Diagnosis.** Infection by an ECHO virus may be suggested by clinical and epidemiologic evidence, but must be confirmed in the laboratory. All the ECHO viruses are cytopathogenic and can be identified by neutralization tests with specific immune serum in cultures of kidney cells from rhesus monkeys. Evidence of infection may be obtained by recovery of the virus from the feces, oropharyngeal swabbings or cerebrospinal fluid, and by demonstration of a related antibody response in the patient's serum. Recovery of virus from the spinal fluid in patients with aseptic meningitis is convincing evidence of an etiologic relation between the agent and the disease. To establish a causal relation between the virus and minor ailments is more difficult.

**Prognosis.** In most instances disease caused by an ECHO virus is self-limited and uncomplicated and progresses rapidly to complete recovery. In cases with involvement of the central nervous system muscular paralysis is an occasional complication. Fatal infection appears to be rare.

**Treatment.** See under Coxsackie virus (p. 527).

**Prophylaxis.** See under Coxsackie virus (p. 527).

## CLINICAL DISORDERS

## ASEPTIC MENINGITIS

A number of ECHO viruses can cause disease with meningeal involvement. Epidemics of aseptic meningitis in separate localities and in different years have been caused by ECHO viruses of types 4, 5, 6, 9 and 16. In individual patients with aseptic meningitis, strains of ECHO viruses, types 4, 5, 6, 9 and 14, have been recovered from cerebrospinal fluid.

In general the clinical features and laboratory findings in patients with aseptic meningitis attributable to an ECHO virus are similar to those in patients infected with a group B Coxsackie virus. There are, however, noteworthy exceptions. The occurrence of muscular weakness and paralysis with associated reflex changes resembling those of paralytic poliomyelitis has been observed in patients infected with a type 2 or a type 6 ECHO virus and suggests that either of these agents may induce neuropathy similar to poliomyelitis in man as well as in monkeys. In many patients with aseptic meningitis attributable to ECHO virus type 9 a fine or blotchy maculopapular erythematous rash is noted, most frequently on the face, during the acute stage of illness. Occasionally tiny ulcerations of the oral mucosa resembling the lesions of herpangina are also seen in infection with some of these viruses, including types 9 and 16. Cervical or generalized lymphadenopathy may be present. ECHO virus type 16 has produced aseptic meningitis in some patients and a rash (Boston exanthem) in others, but both features have not been observed in the same patient. The illness in most patients is self-limited and relatively mild, although the duration and intensity of symptoms are extremely variable.

In patients with aseptic meningitis the blood leukocyte count is usually in the normal range. In infection with types 4 or 6 virus the white cell counts in the cerebrospinal fluid are usually below 500; in cases with type 9 infection they are higher and may exceed 1000. Although polymorphonuclear cells are usually present early in the illness, the cells in type 4 infection may initially be predominantly lymphocytic. The protein content of the fluid is normal or slightly elevated, and the sugar content is normal.

Aseptic meningitis due to an ECHO virus must be distinguished mainly from similar disease resulting from infection by a different virus, especially another virus of the ECHO

group, or a Coxsackie, poliomyelitis or mumps virus. In patients with lymphadenopathy and/or a rash leptospiral infection and infectious mononucleosis have to be considered. The possibility of dual viral infection, especially in patients with muscular weakness or paralysis, must always be kept in mind.

## OTHER ILLNESSES

The role of ECHO viruses in other forms of illness has not been clearly established. The association between ECHO virus type 16 and *Boston exanthem* has been mentioned. This mild disease, affecting mainly children, has clinical similarities to rubella, but can be differentiated by its relatively short incubation period of three to eight days, absence of characteristic lymphadenopathy and a different seasonal incidence. An association between type 18 and possibly other ECHO viruses with diarrhea of infants in the summer months has been noted and an etiologic relationship suggested. As with other minor illnesses, this relationship is difficult to establish with certainty.

## POLIOMYELITIS

Poliomyelitis is an acute viral infection occurring sporadically and in epidemics and characterized by varying degrees of neuronal injury with special localization in the anterior horns and the motor nuclei of the brain stem.

There is a wide range in the clinical manifestations from inapparent infection to complete flaccid paralysis of many muscle groups with the possibility of death from asphyxia and involvement of vital centers in the brain stem.

**History.** Epidemics of paralytic poliomyelitis have been described only in the past century, but there is some evidence that sporadic cases were recognized earlier. The first reference in the medical literature appeared in 1789 (Underwood in England). During the nineteenth century the disease was regarded as a rare affliction of infants, and a small group of isolated cases were accumulated by Heine in 1840 in Germany. The *epidemic* form was not clearly described until 1890 in Europe (Medin in Stockholm) and 1894 in America (Caverly in Vermont). In 1908 Landsteiner produced paralysis in the monkey by intraperitoneal injection of human spinal cord tissue from fatal cases, and the filtrable nature of the virus was established in 1910. A crucial observation was made in 1931 by Burnet and Macnamara that not all poliomyelitis virus strains are immunologically alike. The most significant contribution has been the cultivation of the virus in tissue cultures by Enders, Weller and Robbins. Their findings opened many conceptual and practical areas previously closed by the prevailing notion of the strict neurotropism of poliovirus. Vaccine production has been the most widely heralded of these.

**Etiology.** Three serologic types of virus have been isolated: type 1 (Brunhilde), type 2 (Lansing) and type 3 (Leon). To date *large epidemics* of paralytic poliomyelitis have been caused by type 1, smaller epidemics by type 3, and isolated cases by type 2. Two or more of the types have been recovered during an epidemic, although type 1 has predominated in mixed outbreaks. Many people have been *infected* by all three types as reflected by trivalent antibodies in their serum. The occurrence of two attacks of clinical disease each due to a different serologic type of virus is rare but documented.

Poliovirus is small and hardy and resists many chemicals, including sulfonamides, antibiotics, ether, phenol and glycerin. On electron micrographs the virus appears as a spherical particle. The virus is destroyed by desiccation, strong oxidants such as hydrogen peroxide and potassium permanganate and by the chlorine concentrations generally used in urban water supplies. Under suitable conditions formalin or ultraviolet light may extinguish the infectivity of the virus without abolishing its antigenic capacity, an important point in vaccine research.

Man appears to be the sole virus reservoir in nature, although virus may be recovered from sewage and flies. Until recently the virus

was experimentally demonstrable only by inoculating primates; the response of the chimpanzee is believed to be the closest to that of the natural infection in man. Virus can now be demonstrated in cultures of primate tissues.

For a time infection in rodents could be produced only with strains of the type 2 group, but now members of the other types are capable of infecting them, and one member of the type 2 family has been adapted to grow in the chick embryo. These findings illustrate an important concept, namely, that a strain of virus while retaining its family denomination may undergo changes in pathogenic properties even under natural conditions. Certain strains of poliovirus are more pathogenic for man and monkey than other strains of the same type, a fact which may account for some of the variations in severity in patients and in epidemics.

Recent evidence suggests that ECHO (enteric cytopathogenic human orphan) and Coxsackie viruses may produce a clinical picture indistinguishable from that of nonparalytic and even paralytic poliomyelitis. ECHO and Coxsackie viruses and poliovirus are now grouped together as *enteroviruses*.

**Poliomyelitic infection versus poliomyelitic disease.** Human infection with poliovirus is much more common than poliomyelitic disease. Certain properties of the viruses which cause infection are known from laboratory studies. Less clear are the factors of host-virus relationships which determine the varying clinical consequences of poliomyelitis infection.

**Epidemiology and Public Health Measures.** Epidemics of paralytic disease are seasonal, occurring mainly in the summer and early fall months in the temperate zones, which are the areas most afflicted, e.g., United States, Canada, the United Kingdom, Scandinavian countries, Australia and New Zealand. Significant epidemics have occurred, however, in the Arctic and on tropical islands.

Outbreaks of paralytic poliomyelitis have occurred in winter months in temperate zones. Mild unrecognized cases and their contacts maintain a continuous pool of virus throughout the year. Transmission is largely by personal contact through unrecognized alimentary contamination. Flies, sewage, drinking water, food and milk are potential vectors of infection, but their role appears small. Virus may be recovered from pharyngeal swabs of patients and their contacts for a short time, but the role of pharyngeal drop-

lets in transmission of infection is not clear. It is unwise to assume spread of virus by a single route, even though the predominant one is the oral-fecal circuit.

There is considerable variation in community control measures. The clinical disease when recognized is reportable in most places, usually in two categories, as paralytic and nonparalytic infections. Isolation is recommended by the American Public Health Association for one week from the date of onset or for the duration of fever, if that is longer. Although strict quarantine in urban areas is frustrating and seldom practiced, susceptibles should be kept from known cases and household contacts for two weeks. It has been suggested that poliovirus is not always broadcast widely. Control of personal contacts may therefore be an important factor in limiting spread of virus, especially if vaccination is successful in reducing the incidence of poliomyelitis. The greatest communicability occurs during the latter part of the incubation period and the first week of the acute illness.

The incubation period is usually seven to ten days, but there are extremes of three to thirty-five days. During epidemics it is wise to keep children with unexplained febrile illnesses in bed pending diagnosis.

During epidemics elective operations should be postponed, particularly those of the nose and throat and teeth. Children subjected to tonsillectomy during an outbreak suffer the bulbar type of poliomyelitis approximately ten times as often as the unoperated. If a crucial indication for tonsillectomy arises during an epidemic, it may be wise to administer gamma globulin prior to operation. Tonsillectomy done *at any time* substantially increases the possibility of the bulbar form of the disease should poliomyelitis be contracted in later years.

Evidence indicates that intramuscular injections of certain irritating substances such as alum-precipitated combined antigens of pertussis and diphtheria, given when poliomyelitis virus is widespread, may result in paralysis of the injected limb. Some health officers postpone all but urgent inoculations during epidemics of poliomyelitis.

Although much attention is frequently devoted to environmental sanitation, such efforts do not appear to influence the course of an established epidemic. Swimming pools are often held under suspicion as a locus of infection in view of the opportunities for pharyngeal-fecal contamination. The aggrega-

tion of susceptible children with intimate contact in such places may be important, as may be the tendency for chilling and fatigue from unsupervised play activity.

It is safe to treat patients with poliomyelitis in general hospitals, provided precautions are observed as for typhoid fever.

**Immunity. *Passive immunity.*** Relatively small amounts of injected antibody protect monkeys against oral and intramuscular inoculations of virus. Since many adults have had unrecognized poliomyelitic infections, pools of adult serum (gamma globulin fraction) contain antibody to the three types of virus. A relatively small amount of antibody is capable of preventing or lessening the extent of paralysis. It is presumed that the injected antibody neutralizes the virus during the stage of viremia (see Fig. 160). The practical application of gamma globulin prophylaxis to exposed persons carries many uncertainties and has largely been abandoned.

***Active immunity—naturally acquired.*** The presence of type-specific poliomyelitis antibodies in the serum of many persons with no history of poliomyelitic disease is evidence of the frequent occurrence of nonapparent infections. Poliomyelitis antibody has been found in varying percentages of sampled populations in all parts of the world. Where the attack rate of manifest paralytic poliomyelitis is low in countries with poor sanitation, it is assumed that oral entry of virus occurs early in life, while the infant still has protection from the transplacental passive antibody of an immune mother, and active or passive-active immunity is acquired. In countries with good sanitation there has been a shifting age pattern, infectivity rates being highest in the five- to nine-year groups.

***Active immunity—artificially acquired.*** There are four possible approaches to this phase of control of poliomyelitis: (1) A killed virus vaccine. Formalinized tissue-culture vaccine (Salk) is available. Such a vaccine should be as free as possible of extraneous sensitizing materials. (2) A living, stable, laboratory-developed nonvirulent mutant strain of virus for oral or intramuscular administration. This approach has been the object of important studies by Koprowski and by Sabin. (3) A live virus under protective cover of injected antibody (gamma globulin). There are no examples of this approach in other human viral infections; it has been used successfully in veterinary medicine. (4) Discovery of a virus in the animal kingdom which is antigenically closely related but not

dangerous for man; an example is the original cowpox virus of Jenner.

**SALK-TYPE VACCINES.** The best available and most widely tested vaccine is a formalin-treated monkey-kidney tissue culture filtrate containing the three serotypes of poliovirus. Current practice is to give three injections of 1 ml., respectively; the first two with an interval of one month, and the third seven months after the second. The duration of effective protection and the required frequency of booster injections are under study, as is the question of improving the effectiveness of the vaccine without lessening its safety. The "Cutter incident" in 1954 with the transmission of poliomyelitis from certain batches of vaccine has not recurred. The *Mahoney* strain is used as the prototype 1 virus strain in American and Canadian vaccines; the *Brunenders* strain, which appears devoid of *Mahoney's* property of peripheral invasiveness, is used in the British vaccine.

**Pathogenesis.** Much of the knowledge of the pathogenesis of poliomyelitis has been obtained from experimental disease in other primates. When virus is *fed* to chimpanzees, they seldom become paralyzed. The usual response is the brief appearance of virus in the blood some days later, then in the stools, where it may remain for some weeks, and finally immunity as detected by the development of type-specific antibody. If autopsied, those chimpanzees which had no apparent disease have scattered poliomyelitic lesions in their central nervous systems.

In man the virus generally enters the body through the oropharyngeal route and multiplies in sites unknown, probably in the alimentary tract and in its related lymph nodes and other reticuloendothelial structures. Type-specific antibody is formed; if the response is of sufficient speed and magnitude, the virus particles are neutralized, no clinical disease occurs, and immunity to that type of poliovirus ensues. In this infectivity-antibody contest the virus may proliferate and become invasive before sufficient antibody is formed.

If virus gains direct access to nerve structures or to the blood-lymphatic system, direct infection of the central nervous system may occur. Thus bulbar poliomyelitis occurring soon after tonsillectomy may be due to virus gaining direct access to the medulla through several cranial nerve filaments. Subcutaneously injected virus may follow nerve pathways and cause paralytic consequences initially in the injected limb, as it did in 1935 with the trial of incompletely inactivated

vaccines and in the "Cutter incident" of 1954. There is no evidence that biting insects "inject" poliovirus into man, as they do with the virus of yellow fever.

Factors other than humoral antibody may affect the outcome of the contest between the virus and its human host. These host factors operate at the cellular level, affecting the rate and perhaps the sites of virus multiplication. The occurrence of paralysis has been high in certain families even when not living in the same epidemic area. The role of constitutional physique and nutrition is not certain, but paralytic attacks seem to occur in the robust active child perhaps even more than in the marantic one. The influence of hormonal factors and of stress is evidenced by such observations as (1) the incidence of paralytic disease being higher in pregnant women than in others of similar age; (2) the increased clinical severity of disease with increasing age; (3) the deleterious clinical effect of such stresses as muscular exhaustion, chilling and surgical procedures once the virus has entered the body; and (4) cortisone making certain forms of experimental poliomyelitis more severe.

Clinically the process may terminate at any of the stages shown in Figure 160.

Primary resistance to poliomyelitis apparently depends upon the presence of type-specific neutralizing antibodies. Serologic tests for determining individual antibody level are not readily available, nor is there a skin test for detecting immunity.

**Pathology. Neuropathology.** Unlike most viral infections of the central nervous system, the neuropathology of poliomyelitis is usually pathognomonic; only certain cells and areas of the neuraxis are susceptible to the virus. There is little histologic evidence of meningeal reaction.

Neuronal damage is due directly to virus multiplication. The clinical picture is dependent upon the number and location of involved neurons. The earliest changes consist in lysis of Nissl bodies in the cytoplasm, margination of the chromatin, acidophilic necrosis of the neuron followed by neuronal death, and finally neuronophagia, i.e., invasion by scavenger cells, including polymorphonuclears, plasma cells, lymphocytes and macrophages. Neighboring small vessels reveal perivascular cuffing. Some interstitial glial infiltration occurs, but edema is not an important feature.

Not all affected neurons are killed. The injury may be reversible, and restoration of

function may occur within three to four weeks after onset.

Histologic sections generally reveal more widespread lesions than would be estimated from the clinical findings. Considerable destruction of scattered neurons occurs without clinical disability. Each functionally related neuronal group has a margin of safety which must be exceeded before dysfunction of a vital center and paralysis appear.

The regions in which neuronal lesions occur are (1) spinal cord (anterior horn cells chiefly; to a less degree the intermediate and dorsal horn and dorsal root ganglia); (2) medulla (vestibular nuclei, cranial nerve nuclei and the reticular formation which contains the vital centers); (3) cerebellum (nuclei in the roof and vermis only); (4) midbrain (chiefly the gray matter, but also the substantia nigra and occasionally the red nucleus); (5) thalamus and hypothalamus; (6) the pallidum; and (7) cerebral cortex (motor cortex). The virus spares the following areas, although they are invaded by the viruses of the arthropod-borne encephalitides: (1) the entire cerebral cortex *except* the motor area, (2) the cerebellum *except* for the vermis and deep midline nuclei, and (3) the white matter of the spinal cord. It is the *distribution* of lesions which permits a histologic diagnosis of poliomyelitis.

In relating the neuronal changes to clinical findings the most obvious relationship is the *flaccid paralysis* (cranial and peripheral). The ensuing muscular atrophy is due to denervation plus the atrophy of disuse. The pain, spasticity, nuchal and spinal rigidity and hypertonia of early illness are probably due to lesions of the brain stem, spinal ganglia and posterior columns. The vestibular nuclear lesions may account for the vomiting. When certain vital centers of the medulla are sufficiently involved, dysfunction is reflected clinically by respiratory arrhythmias, blood pressure and vasomotor fluctuations, cardiac arrhythmias, and the like.

**Extraneural pathology.** Although the virus seldom causes lesions outside the central nervous system, secondary lesions do occur elsewhere. The neurophysiologic mechanisms governing other structures are subtle and far reaching. When nervous control of ventilation is disturbed, secondary bronchopulmonary changes occur, viz., aspiration pneumonia, atelectasis and purulent bronchitis, owing to the inability to cough and to interference with thoracic movements. The cardiovascular changes may result in hypertension,

cardiac failure and pulmonary edema. Long-term immobilization leads to negative nitrogen and calcium balances with urinary lithiasis, renal failure, hypertension with encephalopathy and convulsions; thrombophlebitis and pulmonary embolism are less common than might be expected. Treatment itself may cause untoward complications, such as urinary tract infection from improper catheterizations, decubitus ulcers and psychotic disturbances; the virus does not affect the intellectual structures of the cerebral cortex. Ulcerations in the alimentary tract may result in serious bleeding and occasional perforation. Respiratory failure results in anoxic changes and respiratory acidosis.

**Clinical Manifestations.** The diagnosis of acute poliomyelitis rests upon clinical grounds; there is no generally available diagnostic laboratory test. Careful history, close examination of the unclothed patient, and recollection of conditions which may mimic poliomyelitis will obviate most diagnostic pitfalls.

When a susceptible person has had effective contact with poliovirus, one of the following responses may occur: (1) *silent infection*, i.e., asymptomatic and inapparent; (2) *abortive poliomyelitis*; (3) *nonparalytic poliomyelitis*; (4) *paralytic poliomyelitis*. One response may blend into a more severe form. This feature may result in a biphasic course ushered in by a minor febrile illness, a symptom-free interlude of a few days succeeded by a major episode (Fig. 160). Evidence suggests that the order of frequency of the four types of response to poliovirus is that just enumerated, the paralytic response being the least common. Each type of response may result in durable immunity to the immunologic type of virus involved.

**Abortive poliomyelitis.** This presumptive clinical diagnosis is applicable only during obvious poliomyelitis outbreaks, especially in patients known to have been exposed to a clearly recognizable form of the disease. A brief febrile illness occurs, with one or more of the following symptoms: malaise, anorexia, nausea, vomiting, headache, sore throat, constipation and unlocalized abdominal pain. The following are *uncommon* in abortive poliomyelitis: coryza, cough, pharyngeal exudate, diarrhea, localized abdominal tenderness and rigidity. A definitive diagnosis without tissue culture studies is impossible, since the findings are those which precede or accompany a variety of acute disorders. The fever seldom exceeds 103° F., and examina-

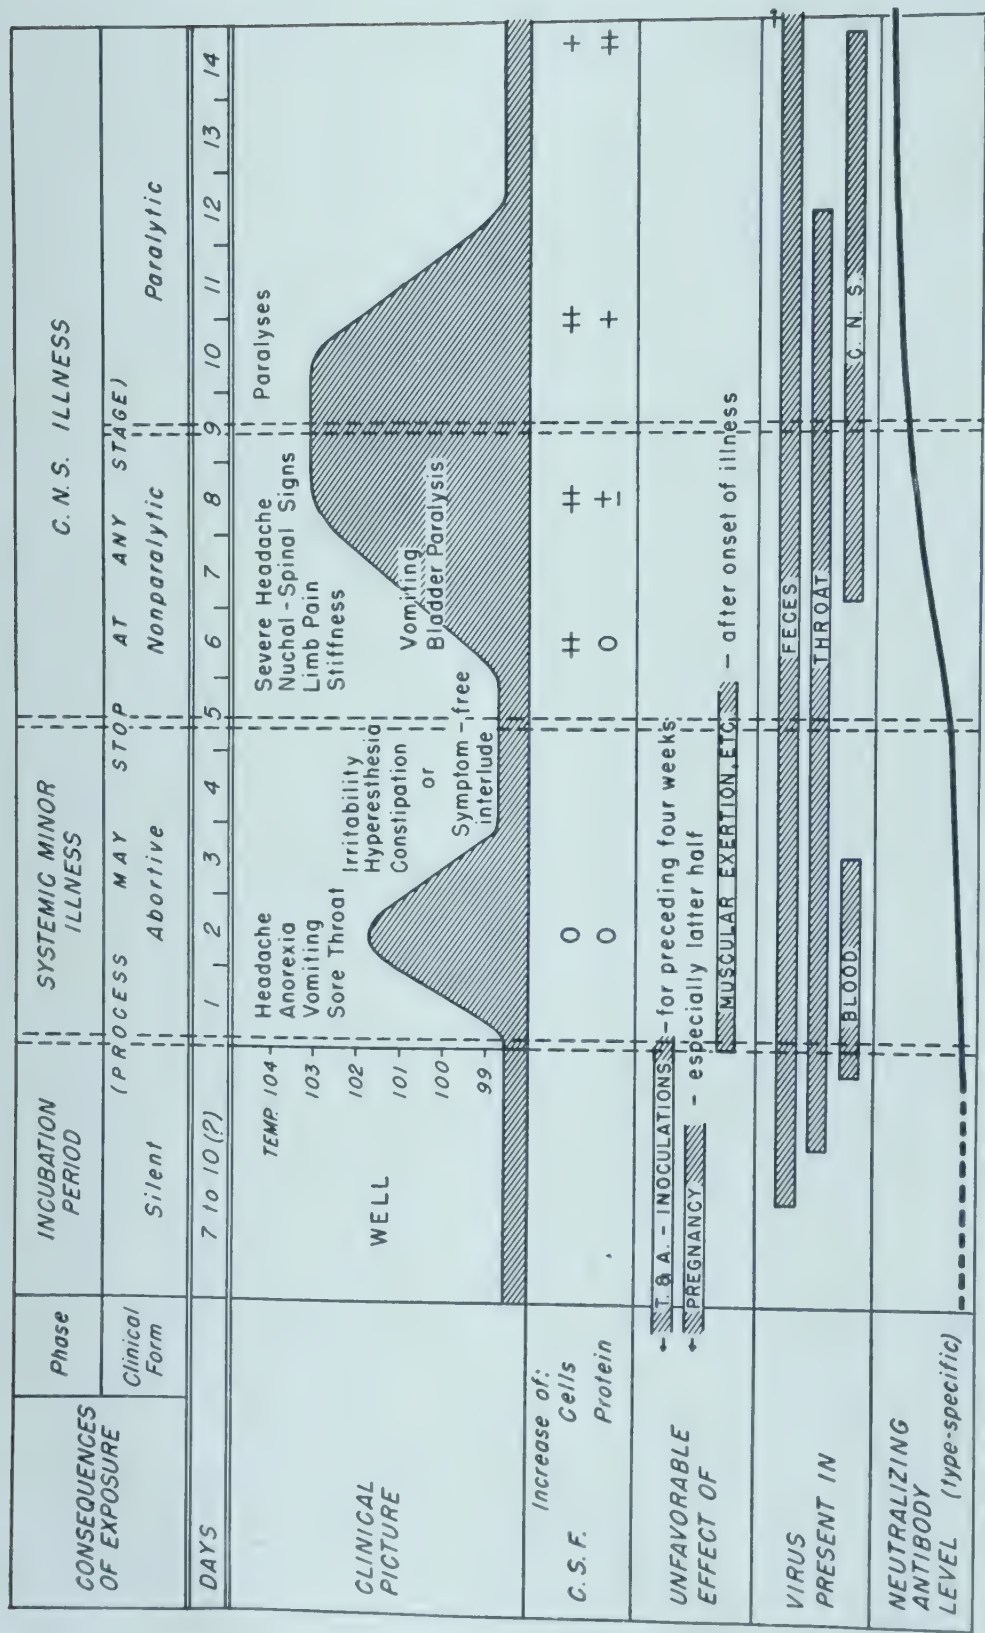

FIG. 160. Schematic representation of major findings in the typical course of clinically biphasic poliomyelitis, which occurs frequently in children, but less so in adults, who tend to have an insidious monophasic course. The evolution of the disease is often compressed into fewer days than shown diagrammatically. Note that virus is present in feces and in throat swabs for relatively long periods, but the viremia period is short. Virus appears in the central nervous system prior to paralysis and tends to disappear in about 10 to 14 days, yet continues to be excreted in the feces. Antibody is present at onset of symptoms and continues to rise. Muscular fatigue does not affect the course adversely unless continued after onset of the minor illness phase, but the influences of tonsillectomy, inoculations and pregnancy are exerted earlier.

tion of the pharynx shows little despite the frequent complaint of sore throat.

During poliomyelitis outbreaks patients presumed to have the abortive clinical form should have complete rest for about a week after defervescence and should be examined carefully about two months later to exclude muscular involvement previously undetected.

**Nonparalytic poliomyelitis.** The subjective symptoms are those enumerated for abortive poliomyelitis, except that headache, nausea and vomiting are more intense, and there is soreness and stiffness of the posterior muscles of the neck, trunk and limbs. Fleeting paralysis of the bladder is not uncommon, and constipation is frequent. Approximately two thirds of the children have a short symptom-free interlude between the first phase (minor illness) and the second phase (central nervous system or major illness) (Fig. 160). This two-phase course is less common in adults, in whom the evolution of symptoms is more insidious. Nuchal and spinal rigidity is a necessity for the diagnosis of nonparalytic poliomyelitis during the second phase.

**DETECTION OF NUCHAL-SPINAL SIGNS.** The signs are first sought by *active tests*. The child is asked to sit up unassisted. If this causes undue effort, if the knees flex upward and he writhes a bit from side to side in sitting up and then places his hands on the bed behind him in the *tripod* supporting position, there is unmistakable spinal rigidity (Fig. 161). While he is still sitting, ask him to flex his chin to his chest and observe whether nuchal rigidity is apparent. Then from the supine position, holding the knees down gently, ask him to sit up and *kiss his knees* (Fig. 162). If the knees draw up sharply or if the maneuver cannot be adequately completed, there is stiffness of the spine due to muscle spasm.

If still uncertain, the *passive tests* should be applied. Gentle forward flexion of the occiput and neck will elicit nuchal rigidity, which may antedate spinal rigidity. Kernig's and Brudzinski's signs are sought.

Next one looks for *head drop* by placing the hands under the patient's shoulders and raising the trunk (Fig. 163). Normally the head follows the plane of the trunk, but in poliomyelitis it often falls backward limply. The frequency of the head-drop sign even in nonparalytic poliomyelitis with no subsequent residuals indicates that it is not due to true paresis of the neck flexors.

In struggling infants it may be difficult to distinguish voluntary resistance from clini-

cally important involuntary nuchal rigidity. One may place the infant's shoulders flush with the edge of the table, support the weight of the occiput in the hand, and then flex the head anteriorly (Fig. 164). Nuchal rigidity that persists during this maneuver may be interpreted as involuntary. When not closed, the anterior fontanel may be tense or bulging as in meningitis.

In poliomyelitis the nuchal rigidity detected in the supine position (Fig. 165, A) often disappears when the patient is turned over. The nuchal rigidity associated with purulent meningitis generally persists in either position (Fig. 165, B). This paradoxical sign, though helpful, is not pathognomonic.

**SUPERFICIAL AND DEEP REFLEXES.** In the early stages the reflexes are normally active and remain so unless paralysis supervenes. Changes in reflexes, either increased or depressed, may *precede weakness* by twelve to twenty-four hours; hence it is important to detect them, especially in nonparalytic patients managed at home.

The *superficial* reflexes, i.e., cremasteric, abdominals, and the reflexes of the spinal and gluteal muscles, are usually the first to be diminished. The status of the spinal and gluteal reflexes helps in forecasting paralysis; they are elicited by tapping segmentally downward on each side of the spine and buttocks. These reflexes may disappear even before the abdominal and cremasteric ones.

Changes in the *deep* tendon reflexes, whether exaggerated or depressed, generally occur eight to twenty-four hours after depression of superficial reflexes and indicate impending paresis of the extremities. There is absence of tendon reflexes with paralysis. Objective evidence of sensory defects 'does not occur in poliomyelitis.

**DIFFERENTIAL DIAGNOSIS.** A wide variety of diseases must be considered in an alert, febrile patient with meningeal signs whose muscle power and reflexes appear intact. In such a patient, when the cerebrospinal fluid reveals pleocytosis, no organisms and a normal sugar level, the differential diagnosis must include all causes of the *aseptic meningitis syndrome*, of viral, leptospiral, fungus, protozoan, helminth or neoplastic etiology (p. 544). Serologic procedures may be helpful in excluding many of these diseases. The diagnosis of nonparalytic poliomyelitis is made by exclusion of other conditions and the epidemiologic probability.

In their early stages *tuberculous* and *purulent meningitis* may simulate nonparalytic

FIG. 161. Tripod sign: characteristic position associated with stiffness of the spine.

FIG. 162. Kiss-the-knee test: ability to complete the maneuver only by flexing the knee. Note tense appearance of the hamstrings.

FIG. 163. Head-drop sign: the head fails to continue in the plane of the body when the shoulders are elevated. This child had nonparalytic poliomyelitis. Tripod and head-drop signs appear in nonparalytic and paralytic poliomyelitis.

FIG. 164. Testing nuchal rigidity in uncooperative, struggling infant: Place the shoulders at the edge of the table, supporting the occiput manually. Flex anteriorly. Only true involuntary rigidity persists.

B

FIG. 165. Supine versus prone postural test for nuchal rigidity in poliomyelitis. A. Nuchal rigidity elicited in conventional supine position. B. In prone position nuchal rigidity disappears in poliomyelitis, but generally persists in pyogenic meningitis. (From A. J. Steigman: Diagnosis and General Care of Acute Poliomyelitis. *Pediat. Clin. North America*, Vol. I, No. 1A.)

poliomyelitis. A lumbar puncture should be done; in addition to bacterial smears and cultures and a cell count, particular attention should be paid to the sugar content, since it is not depressed in the viral infections. Headache, fever and stiffness of the neck and back

with tender extremities may occur in *acute rheumatic fever*, *rheumatoid arthritis* and in *serum sickness*; the cerebrospinal fluid is normal, however, as it also is in the *meningismus* which may accompany the early stages of pneumonia, dysentery, typhoid,

pyelitis and other infections. *Acute tonsillitis* and other conditions associated with cervical adenitis may cause a child to hold his head and neck immobile; this should not be confused with true nuchal rigidity.

**Paralytic poliomyelitis.** The manifestations are those enumerated for nonparalytic poliomyelitis together with weakness of one or more muscle groups, either skeletal or cranial. Symptoms of abortive poliomyelitis may be followed by a symptom-free interlude of several days and then a recurrence of symptoms, culminating in paralysis (Fig. 160). Bladder paralysis of one to three days' duration occurs in approximately 20 per cent of patients, and bowel atony is common, occasionally to the point of paralytic ileus. In infants muscular paralysis may be the first evidence noted.

**CLINICAL CLASSIFICATION.** The distribution of clinical paralysis is characteristically spotty and haphazard. To detect mild muscular weakness it is often necessary to apply gentle resistance in opposition to the muscle group being tested.

**SPINAL FORM.** There is weakness of the neck, abdomen, trunk, diaphragm, thorax or extremities.

**BULBAR FORM.** There is weakness in the motor distribution of one or more *cranial nerves* with or without dysfunction of the *vital centers of respiration and circulation*.

**BULBOSPINAL FORM.** Components of the preceding forms occur together.

**ENCEPHALITIC FORM.** In this form there are irritability, disorientation, drowsiness and coarse tremors not explained by inadequate ventilation. Even during poliomyelitis epidemics this group can be recognized *only* if some peripheral or cranial nerve *paralysis* coexists or ensues. Hypoxia, due to inadequate ventilation from respiratory insufficiency, may itself produce disorientation.

**DIFFERENTIAL DIAGNOSIS. CONDITIONS CAUSING MUSCULAR WEAKNESS.** (1) *Infectious neuronitis* (*Guillain-Barré syndrome*) is the most common and difficult differential problem in this group. Generally the fever, headache and meningeal signs are less marked; characteristically there are few cells, but elevated globulin content in the cerebrospinal fluid. Paralysis is characteristically symmetrical in distribution. Sensory changes and/or pyramidal tract signs are common, but are absent in poliomyelitis. (2) *Peripheral neuritis*—postinjectional, toxic (lead, avitaminosis, and so forth), paralytic cranial herpes zoster, postdiphtheritic neuropathies

—is excluded by history, sensory examination and related findings. (3) Arthropod-borne viral *encephalitis*, *rabies* and *tetanus* have been confused with bulbar poliomyelitis. (4) *Botulism* may closely simulate bulbar poliomyelitis; nuchal-spinal rigidity and pleocytosis are absent. (5) *Demyelinating types of encephalomyelitis* are associated with or follow the exanthems and other infections or occur as an untoward sequel of antirabies vaccination. (6) *Tick-bite paralysis* is uncommon; there is an absence of meningeal signs, and removal of the tick is followed by swift recovery. (7) *Neoplasms* originating in and around the spinal cord may rarely have a fairly abrupt onset. (8) *Familial periodic paralysis*, *myasthenia gravis* and *acute porphyria* are uncommon causes of weakness. (9) *Hysteria* and *malingering* are rare in children.

**CONDITIONS CAUSING PSEUDOPARALYSIS.** In these nuchal-spinal rigidity and pleocytosis are absent. (1) *Unrecognized trauma* as from contusions, sprains, fractures and epiphyseal separation is a common cause of diagnostic confusion. (2) *Nonspecific (toxic) synovitis* produces a limp, usually unilaterally; the hip and the knee are the most common sites. There may be low grade fever for several days. (3) *Acute osteomyelitis* has a more septic course; there is polymorpholeukocytosis, with localized signs, positive blood culture and later roentgenographic changes. (4) In *acute rheumatic fever* the clinical pattern is usually diagnostic. (5) *Scurvy* is revealed by history of inadequate intake of vitamin C and by roentgenographic changes in the bones. (6) *Congenital syphilitic osteomyelitis* of the acute painful type is found only in early infancy; serologic tests are indicated.

**Bulbar and respiratory forms of poliomyelitis.** A number of components acting together may produce insufficiency of ventilation (see Table 76). Adequate ventilation requires (1) intact neural mechanisms, including the rhythmic "drive" from the respiratory centers, and the neuromuscular integrity of the diaphragm and the intercostal muscles, (2) an open airway from the nostrils or lips to the alveoli, and (3) normal hemodynamics, especially of the pulmonary circulation.

The pathology of poliomyelitis is such that any or all three of these factors may become involved clinically. Although it may be convenient to consider the three factors separately, there is close interplay physiologically.

**Table 76. Common Sources of Hypoxia and Hypercapnia in Poliomyelitis**

1. Cranial nerves IX to XII involved, with
  - (a) Pharyngeal paralysis and pooling of secretions
  - (b) Laryngeal involvement—either spasm of laryngeal muscles or paralysis of vocal cords
  - (c) Lingual paralysis
  - (d) Tracheal accumulation of secretions due to inability to cough resulting in aspiration of vomitus
2. Vital center involvement with
  - (a) Inefficient, irregular respiration
  - (b) Cardiovascular disturbance
  - (c) Hyperpyrexia causing increased oxygen consumption
3. Cervical and spinal cord involvement causing paresis of the primary and accessory muscles of respiration
4. Pulmonary complications, viz., pneumonia, atelectasis, edema
5. Contributory factors
  - (a) Panic
  - (b) Gastric dilatation
  - (c) Sedation
  - (d) Inadequate equipment, viz., small-bore tracheotomy tubes, respirator settings, and the like

Thus obstruction to airflow due to paralysis of pharyngeal muscles with accumulated secretions may result in hypercapnia, which may stimulate the respiratory center to speed up its rate, but that particular vital center may be so diseased as to be unresponsive or may be responsive and discharge impulses at an increased rate and depth, but with incomplete response from the effector organs (the muscles of respiration) whose innervation in the cervical and thoracic spinal cord may be involved.

The most serious biochemical changes are the hypoxia and the hypercapnia. These states produce effects on many other systems, such as the cardiovascularrenal.

Respiratory insufficiency should be detected as early as possible in order to diminish its widespread effects. The objective of its management is to maintain normal levels of oxygen and of carbon dioxide in the blood; this requires the proper assessment of the factors contributing most to ventilation failure at any given time; since the situation may shift rapidly, continued clinical analysis is essential.

Despite weakness of the respiratory muscles, the patient may respond with so much respiratory effort that normal alveolar ventilation is maintained. In fact, at the beginning of respiratory muscular involvement, the in-

creased effort (associated with anxiety and fear) may actually produce overventilation, resulting in respiratory alkalosis. Such effort is fatiguing and soon leads to respiratory failure.

For clarity certain terms will be defined: (1) *Pure spinal poliomyelitis with respiratory insufficiency* refers to patients whose respiratory muscles (chiefly the diaphragm and intercostals) develop tightness, weakness or paralysis without discernible clinical involvement of cranial nerves or vital centers. The cervical and thoracic spinal cord segments are chiefly involved. (2) *Pure bulbar poliomyelitis* refers to patients with paralysis of motor cranial nerve nuclei with or without involvement of the vital centers which control respiration, circulation and body temperature. Involvement of the ninth, tenth and twelfth cranial nerves is most important, since there is paralysis of the pharynx, tongue and larynx with resultant obstruction of the airway. (3) *Bulbospinal poliomyelitis with respiratory insufficiency* refers to patients with involvement of the respiratory muscles and with coexisting bulbar paralysis.

The clinical findings resulting from involvement of the *respiratory muscles* are (1) anxious expression; (2) inability to speak without frequent pauses, resulting in short, jerky, "breathless" sentences, which can be demonstrated by asking the patient to count numbers serially; (3) increased respiratory rate; (4) movement of the alae nasi and of the accessory muscles of respiration; (5) inability to cough or sniff with full depth; (6) paradoxical abdominal movements due to diaphragmatic immobility from spasm or weakness of one or both leaves; (7) relative immobility of the intercostal spaces, which may be segmental, unilateral or bilateral. When the upper extremities are weak, and especially when deltoid paralysis occurs, it is well to beware of impending respiratory paralysis, since the phrenic nerve nuclei are in adjacent areas of the spinal cord. In order to bring out minor degrees of paresis, splint the abdominal muscles manually and observe the patient's capacity for thoracic breathing. By lightly splinting the thoracic cage manually, the effectiveness of diaphragmatic movement may be assessed.

The clinical findings of *bulbar poliomyelitis* with respiratory difficulty (other than paralysis of extraocular, facial and masticatory muscles) include (1) nasal twang to the voice or cry, due to palatal and pharyngeal weakness—hard-consonant words such

as "cookie" or "candy" bring this out best; (2) inability to swallow smoothly, resulting in accumulation of saliva in the pharynx and in partial immobility on holding the larynx lightly and asking the patient to swallow. (3) Accumulated pharyngeal secretions may cause irregular respiration, since each inspiration must be "planned" and cannot be "subconscious" in view of the risk of aspirating; the respirations may thus appear interrupted and abnormal even to the point of falsely simulating intercostal or diaphragmatic weakness. (4) Effective coughing is impossible, and constant fatiguing efforts are made to clear the throat. (5) Nasal regurgitation of saliva and fluids due to palatal paralysis with inability to separate the oropharynx from the nasopharynx during swallowing. (6) Deviation of the palate, uvula and/or the tongue. (7) Involvement of vital centers as reflected by irregularity in rate, depth and rhythm of respiration, by cardiovascular alterations which include blood pressure changes, especially upwards, alternate flushing and mottling of the skin, and cardiac arrhythmias; and by rapid changes in body temperature. (8) Paralysis of one or both vocal cords causing hoarseness, aphonia and ultimately asphyxia unless recognized by laryngoscopy and managed by tracheotomy immediately. (9) The "rope sign," an acute angulation between the chin and larynx, due to weakness of the hyoid muscles. The hyoid bone is pulled posteriorly, narrowing the hypopharyngeal inlet.

**Lumbar puncture in poliomyelitis.** This procedure has diagnostic but not prognostic or therapeutic value. In *manifest* cases of poliomyelitis it is not necessary.

Although there are generally less than 500 leukocytes per cubic millimeter, the count may be higher, and rarely there may be no cellular increase. Early the cells are predominantly polymorphonuclear, but they soon become predominantly lymphocytic and decrease to normal numbers as early as ten to fourteen days after the onset. Absence of organisms on smear and culture and normal to elevated sugar content support the diagnosis of poliomyelitis. The protein content in the early stages is normal (up to 40 mg. per 100 ml.) or slightly elevated. Within two to three weeks after onset the pleocytosis diminishes, but the protein content frequently rises to as high as 300 mg. per 100 ml.

**Complications. Gastrointestinal tract.** Striking complications arise occasionally, including melena, which may be severe enough

to require transfusion and is due to single or multiple superficial erosions. Gastrointestinal perforation is rare. Acute gastric dilatation may occur abruptly during the acute or convalescent stage, causing further embarrassment of respiration; immediate gastric aspiration and external application of ice bags are indicated.

**Cardiovascular system.** Mild hypertension of a few days' or weeks' duration is common in the acute stage, probably related to lesions of the vasoregulatory centers in the medulla and to underventilation. Hypertension may appear in the later stages, owing to the protracted immobilization with resulting hypercalcemia, nephrocalcinosis and associated vascular lesions. Dimness of vision, headache and a lightheaded feeling in association with hypertension should be regarded as premonitory of a frank convulsion. Barbiturates, Dilantin or magnesium sulfate therapy is indicated, and a program favoring increased mobilization should be instituted.

Abrupt hypotension rarely occurs and can be controlled only by immediate high pressure intra-arterial or intravenous infusion.

Cardiac arrhythmias are uncommon and vary from unexplained tachycardias, which occasionally yield to digitalization, to a state of abrupt cardiac standstill, for which immediate thoracotomy and manual cardiac massage are indicated.

Acute pulmonary edema occurs occasionally, particularly in patients with arterial hypertension. It should be managed as an acute emergency with autonomic blocking agents for rapid reduction of blood pressure, and inhalation of oxygen bubbled through ethyl alcohol or liquid silicon for an anti-foaming effect.

Electrocardiographic abnormalities indicative of myocarditis are not rare, and varying degrees of histologic changes are observed in fatal cases. Pulmonary embolism is uncommon despite the immobilization.

**Urinary tract.** The transitory paralysis of the bladder in the acute stage has been mentioned. Skeletal decalcification begins soon after immobilization and results in hypercalciuria, which in turn predisposes to calculi, especially when urinary stasis and infection are present together. High fluid intake, a low calcium diet and administration of aluminum gels, hyaluronidase and aspirin have been suggested as preventive measures. A regimen of early active mobilization is desirable.

**Prognosis.** Over-all mortality rates are influenced greatly by the percentage of bulbo-

respiratory cases in any epidemic and by the completeness of reporting nonparalytic cases. With present methods of therapy the overall mortality in large urban epidemics in the United States approximates 5 to 7 per cent. Most deaths occur within the first two weeks after onset. Case fatality rates and the degree of disability appear to be greater after the age of puberty.

Prognosticating the degree of ultimate disability is complex. In general, the more extensive the paralysis in the first ten days of illness, the more severe will be the ultimate disability. Unexpected improvement may appear soon after defervescence and again about six weeks after the onset, a time which corresponds to functional restoration of temporarily inactive neurons. The degree of functional recovery depends also upon the adequacy and promptness of therapy as related to proper body positioning, active motion, use of assistive devices and, of great importance, the psychologic motivation to return to as full and normal a life as possible.

**Treatment.** The broad principles of management are to allay fear, to minimize ensuing skeletal deformities, to anticipate and meet complications in addition to the neuromusculoskeletal ones and to prepare the child and family for the prolonged treatment which may be required and for the permanent disability, if this seems likely. A highly individualized approach with cheerfulness, optimism and candor is of extreme importance.

Patients with the *abortive, nonparalytic* and mildly *paralytic* forms may be treated at home. No antibiotics are effective against poliovirus, and injections of human immune globulin are believed to be ineffective if given after the onset of illness.

For the *abortive* form simple analgesics, sedatives, an attractive diet and bed rest until the child's temperature is normal for several days suffice. Avoidance of exertion for the ensuing two weeks is desirable, and there should be a careful neuromusculoskeletal examination two months later to search for any minor involvement.

Treatment for the *nonparalytic* form is similar to that for the abortive one, relief being indicated in particular for the discomfort of muscle tightness and spasm of the neck, trunk and extremities. Analgesics alone are not as effective as when combined with the application of hot packs for fifteen to thirty minutes every two to four hours. Dry heat as by infra-red lamp is simpler but less

effective in relieving discomfort. Hot tub baths are sometimes useful. A firm bed is desirable and is improvised at home by placing table-leaves or a sheet of plywood beneath the mattress. A footboard should be used to keep the feet at a right angle with the legs. Muscular discomfort and spasm may continue for some weeks even in the nonparalytic form, necessitating hot packs and gentle physical therapy. Such patients should be carefully examined, preferably by a physiatrist or orthopedist, two months after apparent recovery in order to detect minor residuals which might cause postural problems of the spine and feet in later years.

Most patients with the *paralytic* form require hospitalization. A calm, quiet atmosphere is desired. The maintenance of suitable body alignment is necessary to avoid excessive skeletal deformity. A neutral position with the feet at a right angle, knees slightly flexed, hips and spine straight, is achieved by use of boards, shoes, sandbags and occasionally light splint shells. Active and passive motions are carried out by physical therapists as soon as pain has disappeared. Opiates and sedatives are permissible only if there is no impairment of ventilation present or impending. Constipation is common, and fecal impaction should be prevented.

When bladder paralysis occurs, a parasympathetic stimulant such as Urecholine (5 to 10 mg. orally; 2.5 to 5.0 mg. subcutaneously) may induce voiding in fifteen to thirty minutes; some patients do not respond, and others have nausea, vomiting and palpitation. Since bladder paresis seldom lasts more than a few days, intermittent catheterization is preferred to an indwelling catheter; rigid asepsis is necessary, and prophylaxis against urinary tract infection by therapy with a sulfonamide is desirable.

An interesting diet and a full fluid intake should be started at once unless there is vomiting. Additional salt should be provided if the environmental temperature is high or if the application of hot packs induces sweating. Anorexia is common initially and must be combated with clinical and culinary skill. An indwelling polyethylene gastric tube is often necessary to ensure adequate dietary and fluid intake.

The orthopedist and the physiatrist should see these patients as early in the illness as possible, and assume responsibility before fixed deformities develop. Ingenious operations have been devised to counter the skeletal effects of poliomyelitis, particularly inequal-

ity of limb length. Arrest of epiphysial growth in the more normal extremity is more commonly practiced than limb-lengthening operations.

The *management of pure bulbar poliomyelitis* consists essentially in maintaining the airway and avoiding all risk of inhalation of saliva, food or vomitus. Most patients can be treated by suitable position combined with frequent mechanical aspiration of the pharynx. Gravity drainage of accumulated secretions is favored by the head-low (foot of bed elevated 20 to 25 degrees) *prone* position with the face to one side. Aspirators with rigid or semirigid tips are preferred for direct oral and pharyngeal use, and soft flexible catheters may be used for nasopharyngeal aspiration.

A broad-spectrum antibiotic may be given for about a week or until any risk of aspiration pneumonia subsides, but other drugs are contraindicated. Fluid and electrolyte equilibrium is best maintained by clysis, since tube or oral feeding in the first few days may incite vomiting. After the first few days an indwelling polyethylene gastric tube may be used and sips of sterile water given from a spoon with increments as indicated by ability to swallow. In addition to close observation for respiratory insufficiency, the blood pressure should be taken at least twice daily. Hypertension is not uncommon and occasionally leads to hypertensive encephalopathy. An occasional patient with pure bulbar poliomyelitis requires tracheotomy because of vocal cord paralysis or because of a "rope sign" with constriction of the hypopharynx.

The majority of patients with pure bulbar poliomyelitis who recover have little residual impairment, but some patients exhibit mild dysphagia and occasional vocal fatigue with slurring of speech. Generally speaking, the younger the child, the less common are these residual defects.

*Management of respiratory failure due to inadequacy of respiratory muscles* (see also p. 740). This consists essentially in providing artificial mechanical respiration, and familiarity with the equipment selected is essential. The tank respirator (enclosing the entire body except the head and neck) is mechanically more efficient than the cuirass type or the rocking bed, and is the machine of choice in the early management of patients requiring ventilation assistance. In placing a child in the respirator it is essential to conceal any sense of haste or anxiety. The child and the parents should be told what is to take

place; often the presence of the parents at the time of transfer reduces the child's terror and permits smoother synchronization to the machine. Suggestions for regulation of the respirator pressure and rate of respiration are given on pages 737 and 740 and in Figure 208. Clinical evidence of improvement is detected by disappearance of restlessness, pallor or cyanosis, by adjustment to the machine's rhythm with cessation of extra efforts with the accessory muscles, and by a relaxed appearance and ability to doze.

Fever increases the oxygen requirement and should be controlled; in desperate instances the author has used induced hypothermia to reduce oxygen need. During the early febrile days it is better to err on the side of hyperventilation when in doubt. However, if patients are hyperventilated for too long a time, they may become "addicted," making the process of weaning from the respirator more difficult.

The amount of ventilation needed to maintain normal levels of oxygen and carbon dioxide in the arterial blood may vary widely in a short time in the same patient. Since blood gas determinations are not readily obtained and since the oximeter gives no indication of carbon dioxide accumulation, close clinical supervision is required. Respiratory acidosis from accumulation of carbon dioxide may occur despite normal oxygenation abetted by oxygen therapy. The only effective way to remove this excess carbon dioxide is by augmented ventilation.

A combination of positive and negative pressures may be used with a cumulative net effect. A patient on occasion may require minus (—) 25 cm. of water pressure or more, which makes nursing difficult because of inability to maintain a tight seal at the portholes. A combination of negative and positive pressures is then preferred, as for patients with hypotension and poor cardiac filling in whom "atmospheric" pressure, e.g., minus (—) and plus (+) 10 cm. yielding net pressures of 20 cm., is preferable. As with the dose of a drug, the amount of ventilation prescribed must be "enough"; individualized judgment is required for each patient at each of frequent examinations. The thoracic cage of recumbent poliomyelitic patients acquires a lack of compliance or resistance to distensibility, so that pressures required to yield "enough" ventilation may be high.

Measurement of ventilation provides an index of when the patient requires artificial

respiration and is especially useful in establishing the degree of progress during the recovery stage (see p. 736).

**TRACHEOTOMY.** Tracheotomy is required for some patients with pure bulbar poliomyelitis, for some with pure spinal respiratory paralysis and for most patients with bulbo-spinal respiratory involvement. Numerous patients with the combined form, however, have survived without the operation, particularly when highly experienced nursing and medical attention are available constantly. During epidemics it is generally possible for a busy nurse to maintain the airway more readily in respirator patients with a tracheotomy than in those treated by oropharyngeal aspiration alone. The operation is best done with a bronchoscope in situ to maintain ventilation, if necessary by attachment of the anesthetist's manual bag. An opening of the second tracheal ring is preferred, and the largest size tube admissible is inserted in order to reduce resistance to airflow. Collar depressors are available for tracheotomized respirator patients. Standard tracheostomy tubes are often too long for these recumbent, head-low patients and may impinge upon the anterior tracheal wall, so that it may be advisable to cut 1 to 2 cm. from the distal end. Frequent but swift endotracheal aspiration is required and is facilitated by instillation of a broncholavaging solution such as saline solution with or without added antibiotics, decongestants or enzymes, such as trypsin. Humidification of air or oxygen is an important feature in preventing inspissation.

The tracheotomized patient with bulbo-spinal poliomyelitis differs from patients tracheotomized for other acute airway problems in being unable to cough, frequently for many months. Tubes should not be removed too early, but may be corked and left in place for many months until the patient has some tussive strength restored. Plastic buttons and tubes used for this purpose have the advantage of less weight and less irritation.

Electronically activated mechanical devices ("exsufflators") are being devised to produce periodically high pressures on the chest wall of respirator patients during exhalation, thus forcing the bronchial secretions toward the glottis. These intermittent cycles can be established by the use of a vacuum cleaner whose hose is inserted through a port-

hole; when a high negative pressure is built up, sudden opening of the large bedpan port will produce exsufflation. Convalescent respirator patients whose cough is ordinarily feeble can be trained to clear their bronchi several times daily by coughing while the chest is squeezed together by the attendant.

**Antibacterial prophylaxis** with an antibiotic to prevent respiratory infection is desirable for patients with respiratory difficulties. Penicillin in large doses is preferred for the initial administration, pending results from nasopharyngeal and tracheal cultures to determine the susceptibility *in vitro* of the bacteria to various antibiotics.

**Weaning a patient from dependency on a respirator** during convalescence is a part of the necessary rehabilitation. Much depends upon the initial psychologic and physical handling of the patient. The respirator should be opened periodically even if only for a few seconds, beginning on the first day of acute illness. Strong verbal reassurance is given to the patient. Gradually the pressure settings are lowered unobtrusively and the periods out of the respirator increased in duration and frequency. Cuirass respirators and the rocking bed are valuable devices in the weaning process, during which fatigue must be avoided. Speech therapists may be helpful in training these patients in breathing methods, including the glossopharyngeal one. The weaning from respirators and the total rehabilitation of the severely involved ex-respirator patient may require several years of active work plus a supervised program for life.

## ACUTE ASEPTIC MENINGITIS SYNDROME

The above title is applied to a clinical syndrome involving the central nervous system of infants and children which may be caused by a variety of etiologic agents. The descriptions of a number of these agents and the diseases they cause are given under their appropriate headings elsewhere in the book. In this chapter an attempt is made to summarize the possible causes and diagnostic criteria of the recognized etiologic entities. An arbitrary and broad criterion is accepted as the basis for diagnosis, namely, that there is a pleocytosis without visible etiologic agents in the stained smear.

**Clinical Pattern.** The onset is variable; central nervous symptoms often occur suddenly in an apparently healthy child; there may be a history of a nonspecific grippelike illness seven to ten days previously from which recovery seems to have been complete; or the child's health may have gradually deteriorated during the preceding one to two weeks. The presenting symptoms and signs vary and depend somewhat on the age of the child. The striking complaint of the older child is headache. In the infant the presence of headache may be inferred from his irritability and resentment at being touched, or convulsions may be the initiating symptom. Anorexia, nausea or vomiting is frequently present. There is some stiffness of the neck and back, but it may be slight; the presence of Kernig's sign is variable. In the infant, bulging of the fontanel indicates increased intracranial pressure; in the older child it may be sufficient to cause fullness of retinal vessels or papilledema. Careful neurologic examination may detect localized paresis of muscle groups or localized changes in sensation.

The only consistent laboratory finding is an increase in cells in the cerebrospinal fluid, which ranges from 20 to several thousand cells per cubic millimeter. The cells are characteristically mononuclear, but many may be polymorphonuclear. The cerebrospinal fluid sugar and protein are normal or slightly elevated.

**Approach to an Etiologic Diagnosis.** The clinical pattern just described can be caused by any of the agents listed in Table 77. A careful analysis of the history is probably the most important clinical factor. The following points should be considered: (1) the age and sex of the patient; (2) the season of the year and the geographic location; (3) the

presence of similar cases or of communicable diseases in the community; (4) associated illness among animals in the community or the possibility of contact with sick or dead animals.

During the summer and early fall the possibility of *nonparalytic poliomyelitis* comes first to mind, especially if there are known cases of paralytic poliomyelitis in the community. Many of the outbreaks and cases called "nonparalytic poliomyelitis" are due to such other enteroviruses as the Coxsackie and ECHO ones (see p. 526). This is especially so when there are concomitant cases of pleurodynia and of unexplained rashes with meningismus. *Mumps encephalitis* is much more common in boys than in girls and can occur without any of the usual manifestations of this disease. A history of swimming in possibly contaminated rivers or streams should suggest the possibility of *leptospirosis*; *L. icterohaemorrhagiae*, *L. canicola* and *L. pomona* can all cause this syndrome without evidence of jaundice. Contact with dogs, cattle or pigs or with a rat-infested environment would also suggest the possibility of *leptospirosis*. A summer epidemic in the middle West or the West should raise the possibility of one of the *arthropod-borne encephalitides* and, if associated with enzootics among horses, would suggest *Eastern* or *Western equine encephalitis*. A sporadic illness might suggest *lymphocytic choriomeningitis*, particularly if there is a history of contact with mice.

In addition to mumps, the aseptic meningitis syndrome may be associated with such other communicable diseases as measles, German measles or chickenpox, or it may be the first manifestation of such diseases as herpes simplex, herpes zoster, infectious hepatitis, primary atypical pneumonia and infectious mononucleosis.

Patients with *purulent meningitis*, particularly *H. influenzae*, may have clinical manifestations that simulate this syndrome when seen early in the disease or if the clinical course has been modified by suboptimal antibiotic therapy. The cerebrospinal fluid should always be cultured even though it is clear. *Tuberculous meningitis* may present a difficult diagnostic problem. A careful evaluation of contacts, a positive tuberculin reaction and other points in the history and physical examination (see p. 469) may indi-

Table 77. Clinical Conditions Which May Induce the Acute Aseptic Meningitis Syndrome\*

Agent	Disease
I. Infectious	
A. Viral	
1. Established viral origin	
Transmitted:	
<i>Man to man:</i> Viruses of poliomyelitis, mumps, herpes simplex, herpes zoster, Cocksackie, ECHO, primary atypical pneumonia, infectious hepatitis	
<i>Rodent to man:</i> Lymphocytic choriomeningitis	
<i>Arthropod to man:</i> The arthropod-borne encephalitides, including Eastern, Western Equine and St. Louis	
2. Presumed viral origin	Infectious mononucleosis, infectious lymphocytosis
B. Bacterial	
1. <i>M. tuberculosis</i>	
2. Bacteria causing purulent meningitis	(1) Very early meningitis (2) Meningitis modified by partial suppression of organisms by suboptimal antibiotic therapy
C. Spirochetal	
1. <i>Leptospira icterohaemorrhagiae, canicola, pomona</i>	Leptospirosis
2. <i>Treponema pallidum</i>	Syphilis
D. Protozoal	Toxoplasmosis
E. Helminthic	Trichinosis
II. Postinfectious or allergic	
A. Natural infections	Rubeola, rubella, varicella, variola, mumps
B. Vaccinations	Smallpox vaccination, rabies vaccination
III. Noninfectious	
A. Meningeal irritation from contiguous lesion	Lesions within or adjacent to the central nervous system, including abscesses, granulomas, hematomas, tumors, thromboses
B. Allergy	
1. After vaccinations or infections	See under <i>Postinfectious or allergic</i>
2. Tuberculosis	Presumably a sensitivity reaction occurring in tuberculous children without actual infection of the meninges
3. Other allergic reactions	e.g., Serum sickness
C. Toxins or irritants	
1. General poisons	e.g., Lead, arsenic, bacterial
2. Intrathecal injections	e.g., Serum, antibiotics, Lipiodol or air

\* Cerebrospinal fluid shows a leukocytosis, often polymorphonuclear early and lymphocytic after the first few days, but no organisms can be detected on a stained smear. The etiologic agent is not necessarily demonstrable in the central nervous system.

cate the correct diagnosis. *Trichinosis* is suggested by a high eosinophile count in the peripheral blood and by other signs compatible with this disease. Finally the possibility must be recognized that the meningeal reaction may be noninfectious in origin, resulting from the reaction to (1) a contiguous lesion (tumor, abscess, and the like) in the brain, spinal cord or their bony covering; (2) a toxin such as lead; (3) an intrathecal injection; or (4) an allergen.

**Treatment.** Symptomatic measures for headache, fever, vomiting and muscle sore-

ness are useful. As the etiologic diagnosis often remains in doubt, hospitalized patients should be as strictly isolated as those with the most infectious of these causes, which is probably mumps, unless that diagnosis can be eliminated by virtue of a known previous attack. It is important to examine the patient carefully several weeks after apparent recovery for assessment of muscular function to detect any weakness which may have eluded recognition.

ALEX J. STEIGMAN  
T. F. McNAIR SCOTT

The limited types of response of the central nervous system to noxious influences make it impossible to distinguish the manifestations of disturbances due to inflammation (encephalitis) from those due to other causes, e.g., hypertension (encephalopathy). Although, in general, such a distinction can be made by the association of cerebral manifestations with other evidences of infection, or with a systemic illness of noninfectious origin, it is important to remember that such an association does not constitute an absolute diagnosis. For instance, a convulsion in the presence of a viral pneumonitis may not result from encephalitis due to the infectious agent itself, but from an encephalopathy associated with a physiologic disturbance such as a remediable electrolyte imbalance.

Of the groups of infectious agents that cause encephalitis, the most frequent are the viruses, so that the term "encephalitis" has almost become synonymous with viral encephalitis. Other agents, however, including bacteria, fungi and helminths, can cause encephalitis as they can the aseptic meningitis syndrome (see p. 544). The discussion will be confined to encephalitides of known or suspected viral origin.

**Clinical Manifestations.** Regardless of etiology, the central nervous system responds by reactions which are predominantly meningeal, encephalitic, myelitic or radicular. When two or more of these reactions occur together, such terms as "meningoencephalitis" or "meningoencephalomyelitis" are used.

**Meningeal.** This is the most common and is described in detail elsewhere.

**Encephalitic.** Characteristically, there is a history of sudden or insidious onset of headache, followed by drowsiness which may proceed to deep coma. Fever is usual. A convulsion may be the initial symptom; this is common in infancy, but decreases in frequency with age. Sometimes the onset is marked by hyperactivity, bizarre behavior or mental disturbance. Palsy or paresis of one or more cranial nerves, disorder of speech, ataxia, weakness of muscle groups, diplopia, alteration of reflexes and disturbances of the autonomic nervous system are usually found as single or combined signs. The cerebrospinal fluid is often within normal limits by routine tests; however, there may be a moderate leukocytosis, in which lymphocytes usually predominate after the first forty-eight hours, although a high percentage of polymorphonuclear cells may be present early.

The sugar content is usually normal, but on occasion it may be low; the protein content is either normal or moderately elevated. Recovery may be dramatically sudden within a few hours after the onset or may be delayed for days, weeks or months. Permanent residual damage may result at all ages, although the incidence appears to be much greater in very young infants and decreases with increasing age. The presence of persistent neurologic involvement is evidenced by such symptoms as convulsive attacks, hemiplegias or monoplegias, bizarre behavior patterns and mental retardation. Residual damage may not be immediately obvious, but may manifest itself later as a deficiency in motor skills or learning ability. Apart from permanent residuals, transient neurologic changes and behavior disorders may be noted shortly after apparent recovery from the acute phase.

**Myelitic.** The onset is usually insidious. There is often paresthesia of the lower extremities followed by weakness; weakness may be the initial symptom as in poliomyelitis. Sphincter disturbances are common, early manifestations. There may be a monoplegia, a paraplegia or paralysis of various muscle groups which may be symmetrical. Recovery is slow and often incomplete. In Landry's type of paralysis the lower extremities are first involved, and the paralysis ascends until it fatally affects the respiratory center, the sensorium remaining clear. The cerebrospinal fluid usually shows an increase in cells with an accompanying increase in protein. Sugar is usually normal.

**Radicular.** Root pain may be a presenting symptom as in herpes zoster, or there may be widespread peripheral neuritis, as in Guillain-Barré's syndrome.

**Pathology.** The pathology of the encephalitides can be considered under several headings: (I) rabies and von Economo's disease; (II) arthropod-borne encephalitides; (III) inclusion body encephalitides, (a) herpesvirus groups and subacute inclusion encephalitides, (b) cytomegalic inclusion disease; (IV) the demyelinating encephalitides. These divisions are useful as general guides, although there is considerable overlapping and variation of severity within each group.

**I. Rabies and von Economo's disease.** The cortex is relatively free from lesions, while the basal structures are most involved.

(a) **RABIES.** There is congestion and lymphocytic infiltration in the meninges, especially near focal parenchymal lesions in

which degeneration of nerve cells occurs. The medulla, pons and midbrain are predominantly affected. The cortex, except for the hippocampus, tends to be spared. Advanced degenerative changes may occur in the gray matter of the cord. The presence of Negri bodies in the cytoplasm is characteristic of degenerating and even of apparently normal neurons. These are eosinophilic, oval or round, and contain basophilic granules. As nerve cells degenerate, neuronophagia occurs. In severely affected areas there is hyperemia with occasional perivascular hemorrhage, and perivascular infiltration with lymphocytes and polymorphonuclear cells.

(b) VON ECONOMO'S DISEASE. Here again neuronal degeneration is the characteristic finding with satellitosis and neuronophagia. Perivascular lymphocytic infiltration occurs focally. Necrosis with liquefaction is occasionally found. The midbrain and basal ganglia are most often affected. Glial scarring may be marked, especially in the area of the substantia nigra.

II. *Arthropod-borne (ARBOR) viruses*. Characteristically, all parts of the brain, including the cortex, are involved. The striking findings are those of acute inflammation involving mainly the cerebral cortex, the thalamus and basal ganglia. The cerebellum and the spinal cord are frequently and extensively affected. The brain may be grossly hyperemic. Histologic lesions are widely scattered throughout gray and white matter. These consist of perivascular and parenchymal infiltration initially by neutrophils and later by lymphocytes; focal areas of demyelination, and foci of total necrosis of all elements with intense infiltration by polymorphonuclear cells. Punched-out areas of acute neuronal degeneration are found without inflammatory reaction. Cavitation eventually may occur in these areas. These encephalomalacic areas suggest vascular involvement, although none can be demonstrated.

III. *Inclusion body encephalitides*. The cortex is extensively involved, although the basal ganglia and cord are not spared and may sometimes predominate.

*Herpesvirus and subacute inclusion encephalitis*. The characteristic of this group is the presence of type A intranuclear inclusion bodies. These are large inclusions occurring in disorganized nuclei. They are often hard to find in sections and are more often in the oligodendria than in the neurons.

1. *HERPESVIRUS INFECTION*. (a) *HERPES SIMPLEX (HERPESVIRUS HUMANI)*. Gross softening of the brain is charac-

teristic. The meninges are infiltrated by lymphocytes, large mononuclear cells, plasma cells and, less often, neutrophils. The cortex is most involved, especially the outer layers, as if the process were extending in from the meninges; the basal ganglia and the cord are little affected. The lesions contain large numbers of nerve cells undergoing necrosis; satellitosis and neuronophagia occur, and the damaged area becomes infiltrated with macrophages or remains rarefied without cellular reaction; early gliosis may be found at the margin of the lesions; demyelination of the associated white matter may occur.

(b) *HERPES ZOSTER (HERPESVIRUS VARICELLAE)*. Intense inflammatory changes occur in the posterior root system, and the posterior gray and white matter of the cord, pons and medulla. The nerve cells of the affected posterior root ganglia show degenerative changes, but only occasionally intranuclear inclusion bodies. Inclusion bodies can be found in the nucleus of the capsular cells of the posterior root ganglia, in the sympathetic ganglia, in the neurilemma cells of peripheral nerve twigs and in the nerve cells of the myenteric plexus.

(c) *B. VIRUS (HERPESVIRUS SIMII)*. Involvement of gray and white matter of the cord may predominate. Focal areas of necrosis, perivascular cuffing and congestion of vessels are spread throughout the central nervous system. Demyelination is prominent and is secondary to the extensive necrosis.

2. *SUBACUTE INCLUSION ENCEPHALITIS*. The changes are similar to, but not as acute as, those found in herpes simplex infection. Widespread perivenous mononuclear cell infiltration is present; neuronophagia and diffuse astrocytosis occur. The basal ganglia and cord tend to be more involved than in herpetic infection (see p. 552).

*Cytomegalic inclusion disease* (see also p. 524). The affected cells in this disease grow to enormous size and contain both nuclear and cytoplasmic inclusions. The nuclear inclusions are granular, eosinophilic to basophilic and are surrounded by a halo. The cytoplasmic inclusions are numerous, small and basophilic without a halo. The nervous system is affected only under the age of two months. The periventricular matrix and olfactory tracts are particularly affected, and calcium and iron salts are deposited in these areas. Inclusions can be seen in the astrocytes of the subependymal matrix, less commonly in the endothelium of the blood vessels and rarely in the neurons.

IV. *Demyelinating encephalitides*. These

include the encephalitides associated with certain exanthems and vaccination procedures. The pathologic changes in all of them involve the white matter of the cortex, basal ganglia and cord, where initial perivenous loss of myelin is followed by infiltration of microglial cells. When involvement is acute, diapedesis of red cells occurs, giving rise to acute hemorrhagic leukoencephalitis. The meninges are involved first at the septa where the large veins of the cord reach them.

**Etiology.** Many different viruses may be responsible for encephalitis, and in recent years a number of previously unknown ones have been isolated from patients with encephalitis. Some of these diseases are considered in separate chapters. Here the approach is more general and the major groups of viruses are considered with special comments on some of them. The incidence of any one etiologic type of encephalitis will vary with environment. For instance, arthropod-borne encephalitic viruses are almost unknown in the urban centers of the eastern United States, while they are responsible for epidemics and sporadic cases in both rural and urban communities in the Middle and Western States and the insect-ridden areas of the tropics. Subclinical or systemic infections without central nervous system involvement with potentially encephalitogenic viruses appear to be common; reservoirs of encephalitic viruses exist among lower animals.

The encephalitides described here are arbitrarily divided into two groups: (I) those in which a viral etiology is known or strongly suspected; (II) the demyelinating group not directly of viral origin.

**Viral etiology.** **ARBOR (ARTHROPOD-BORNE) VIRUSES.** These viruses are transmitted by mosquitoes, ticks and mites. Although many viruses of this group exist in nature as endemic infections of lower animals, especially birds, relatively few are known to be encephalitogenic for man. The latter include encephalitides due to Eastern and Western equine, Venezuelan, St. Louis, Japanese B., Murray Valley, West Nile, Russian Far Eastern or spring-summer (closely related to, if not identical with, louping ill, a tick-borne disease of sheep), Mengo (apparently identical with the virus of encephalomyocarditis, EMC virus) and dengue.

For a number of these virus infections the animal hosts and the arthropod vectors are known. Birds appear to be the major reservoir for Eastern and Western equine and St. Louis viruses.

A pattern of host-parasite relationship has been demonstrated for certain of these infections; for instance, St. Louis virus may be spread as follows: The virus exists in the chicken mite (*Dermonyssus gallinae*) and can be passed transovarially from one generation to another; bites from infected mites cause a transient viremia in the host bird without clinical illness; this provides a source of virus for other mites and also for accidental infection of the mosquito vector (*Culex tarsalis*), which carries the virus to man.

**NONARTHROPOD-BORNE VIRUSES.** This heterogeneous group is being increased by the identification of new viruses, including the following.

**ENTEROVIRUSES.** There are many viruses present in the human intestine which are associated with no disease or with nonspecific febrile illnesses. However, in three recognized groups certain of their members can affect the central nervous system and produce aseptic meningitis, encephalitis or myelitis with resultant transient or permanent paralysis of muscle groups. These three groups are (a) *poliomyelitis* types I, II, III (see p. 531); (b) *ECHO* (enteric cytopathogenic human orphan), (see p. 529) particularly types 4, 5, 6, 7, 9, 14 and 16; (c) *Coxsackie* (see p. 526), particularly Types 1, 4, 7, 8, 9, 10 of group A and all five of group B.

**MYXOVIRUS GROUP.** (a) *Mumps* (see p. 505). Some involvement of the central nervous system occurs in about 25 per cent of patients with mumps. Most frequently this manifests itself as an aseptic meningitis, but cases of true encephalitis or encephalomyelitis are recognized, and these may be associated rarely with transient or even permanent weakness of muscle groups or nerve deafness.

(b) *Influenza* (see p. 508). Encephalitic symptoms occur in certain patients with influenza, and a neurotropic strain of influenza virus has been isolated in the laboratory. However, the evidence that influenza virus causes encephalitis by direct invasion in man is not firmly established.

**HERPESVIRUS GROUP.** (a) *Herpes simplex* (*Herpesvirus hominis*) (see p. 490). Primary infection by this virus may cause either an aseptic meningitis or a meningo-encephalitis with symptoms of encephalitis. When the central nervous system is involved, there are often no other manifestations, but on occasion there may be such manifestations as stomatitis, conjunctivitis and, especially in the newborn, hepatitis.

(b) *Herpes Zoster* (*Herpesvirus varicellae*) (see p. 497). Pain from involvement of the posterior root ganglion supplying the dermatome presenting the vesicular eruption is characteristic of this infection. Occasionally the virus is responsible for meningoencephalitis with cranial nerve paresis or paralysis of the limbs.

(c) *B. Virus* (*Herpesvirus simii*). This virus causes an enzootic infection in monkeys, the natural history of which is similar to that of herpes simplex infection in man. When man is infected, either by an actual bite or by contamination of cuts by infected saliva or even by infected monkey kidney cells in tissue culture, a highly fatal type of encephalomyelitis occurs, which often takes the form of a Landry's type of ascending myelitis. The incubation period is two to three weeks.

(d) *Subacute Inclusion Encephalitis*. This is suspected but not proved to be of viral origin. The disease has a gradual onset and is progressive for months or years to eventual death. The course is generally afebrile. Mental symptoms occur early and progress to dementia. Apart from these, such manifestations as aphasia, hallucinations, cranial nerve weakness, optic atrophy, "startle attacks," hyperkinesia, muscular rigidity, seizures of various kinds, periodic rhythmic jerking of one or more limbs and periodic loss of muscle tone have been reported. This is chiefly a disease of childhood and early adolescence.

MISCELLANEOUS VIRUSES. (a) *Lymphocytic choriomeningitis* (L.C.M.). The causative virus is enzootic in mice, and man may be incidentally infected. After an incubation period of one to three weeks the patient suffers a grippelike illness for three to seven days to be followed, typically, by development of an aseptic meningitis, although symptoms of encephalomyelitis may predominate. The virus can be isolated from the blood and cerebrospinal fluid. Occasionally only the systemic manifestations occur, and a fatal pneumonitis without central nervous system involvement has been described. Recovery from the meningeal manifestations is the rule, although a progressive fatal arachnoiditis has followed the acute infection. Residual damage of some degree is usual after the encephalomyelitic forms.

(b) *Von Economo's disease* (*Encephalitis lethargica*). This clinical entity was described as occurring in epidemic form for about ten years, beginning in 1917. The etiology was

not identified, although a viral one was strongly suspected. In epidemics the clinical manifestations were of two main types: (1) somnolence and ophthalmoplegia and (2) hyperkinesia. Both types could occur successively in an individual patient. The striking feature of this infection was the insidious occurrence of severe sequels in apparently recovered patients. These might be manifested as parkinsonism; disturbances of sleep rhythm; behavior disorders; and especially typical were the so-called oculogyric crises, in which the child stopped all activity and often lay down, while spasms of the ocular muscles rolled the eyes upward and held them fixed for varying intervals of time.

(c) *Rabies* (see p. 512). This virus is transmitted by the bite of infected animals, including bats, and produces a fatal encephalomyelitis.

(d) *Measles* (see p. 483). It is highly probable that encephalitis occurring at the onset of measles is due to the virus of measles, while the more usual late-occurring encephalitis should be classified as postinfectious.

(e) *Benign Myalgic Encephalitis*, or *Iceland or Akrureyri disease*. This epidemic disease was first noted in Iceland, but has occurred since in various parts of the world. Its etiology is unknown. The clinical picture is characterized by pain and tenderness in the nape of the neck, back and limbs and sometimes paresis of various muscle groups accompanied by low grade fever coming on abruptly or more often insidiously after an incubation period of one week. Relapses with paresis of other muscles may occur after intervals as long as eight weeks. Paresthesia and hypalgesia are common. Deep tendon reflexes may be decreased. There is rarely evidence of nuchal rigidity, and the cerebrospinal fluid is not altered. Improvement may occur in a few days, but residual signs and symptoms of muscle and nerve involvement may persist for as long as six years after the acute episode. Adolescents have been chiefly affected; it is rare under the age of five years.

(f) Certain other diseases of viral or suspected viral origin such as infectious mononucleosis (see p. 518), infectious hepatitis (see p. 704) and some of the adenoviruses (see p. 747) may be responsible for symptoms of meningoencephalitis.

*Demyelinating encephalitides*. POST-INFECTIOUS ENCEPHALITIS. This name is applied to the encephalitic manifestations that

occur as complications of certain systemic infections. They are fairly common in measles (1 per 600 to 1000 cases), less common after German measles (1 per 6000 cases) and smallpox (1 per 2000 cases) and rare after chickenpox. It seems probable that some patients with mumps may have a post-infectious form of encephalitis in addition to or without a preceding viral encephalitis. A similar complication has been described as occurring after upper respiratory tract infections. It is possible that such encephalitides may be shown in the future to be due to an adenovirus or some yet unidentified respiratory virus.

**POSTVACCINAL ENCEPHALITIS.** This occurs as a complication of smallpox vaccination (1 per 4000 to 100,000; see p. 504) and antirabies vaccination (1 per 3000 to 7000; see p. 515).

Extensive demyelination is characteristic of this group of encephalitides, regardless of the primary disease. These findings are generally attributed to an antigen-antibody reaction resulting from development of antibodies against nervous tissue. Some alteration of brain substance to make it antigenic, possibly as the result of initial viral damage, is thought to occur. An identical pathologic picture can be produced in animals by injecting them with brain substance in association with adjuvants.

Encephalitic symptoms may also occur after vaccination against pertussis, influenza and poliomyelitis and have been encountered after yellow fever vaccination in infants under one year of age.

Transient encephalomyelitis, usually associated with optic neuritis, may be the initial evidence of multiple sclerosis which becomes clinically definite in late adolescence or early adult life.

**Epidemiology.** This varies with the infecting agent. An exact etiologic diagnosis is almost impossible to make clinically, but an epidemiologic approach may afford the basis for a well educated guess. For instance, an arthropod-borne viral infection might be suspected in a summer epidemic when suitable vectors were present in the environment, whereas a sporadic case of encephalitis might lead to a diagnosis of lymphocytic choriomeningitis if exposure to mice was elicited. Epidemics of encephalitis due to one of the enteroviruses can be recognized only when the presence of such an agent in the community has been identified in the laboratory.

**Diagnosis.** Etiologic diagnosis is possible only by laboratory methods (see p. 384) either by isolation of the virus from blood or cerebrospinal fluid, from brain, or from nasopharyngeal or rectal swabs, or by demonstrating a rise of antibodies against a known virus.

**Treatment.** Although no specific therapy is available for this group of diseases, the skillful application of supportive and symptomatic measures is of prime importance. These can be summarized as follows:

**Acute phase.** **AIRWAY.** The throat may need to be cleared by suction and at times an airway inserted, or a tracheotomy may be needed. Significant irregularities of respiration are not rare, and artificial respiration may be required to eliminate carbon dioxide (see pp. 736 and 740).

**CONVULSIONS.** These must be controlled by appropriate means (see p. 1117).

**FLUIDS AND NUTRIENTS.** These are given intravenously if necessary, and then by gavage tube until the patient is ready to take foods by mouth. Careful control of electrolyte balance is essential to avoid water intoxication, which can occur easily in disease of the central nervous system (see p. 191).

**GENERAL MEASURES.** These may include administration of oxygen when necessary; reduction of temperature by sponging and aspirin; frequent turning; emptying of the bladder by the use of cholinergic drugs, skilful Credé or, as a last resort, catheterization; emptying of the bowel; and maintenance of adequate sedation.

**SPECIAL MEASURES.** *Broad-spectrum antibiotics* should be given routinely to prevent secondary infection such as aspiration pneumonia. Definite evidence of the 'value of corticosteroids is lacking. However, it seems reasonable to use one of them in pharmacologic doses (6 to 8 mg. per kilogram of body weight per day) for two to three days, with decreasing doses during the next three to four days. Such therapy may prevent edema, by decreasing capillary permeability, and possibly, early gliosis. When there is increased intracranial pressure, *burr holes* for tapping ventricles or *craniotomy* for temporal flaps may be necessary. *Hypothermia* may be effective in lowering the body temperature and may thus decrease cerebral metabolism and oxygen consumption and the body's insensible water loss.

**Convalescent care.** Anticonvulsant therapy may be necessary for several months, and serial electroencephalograms may be

helpful in following the course. Physiotherapy, occupational therapy and corrective surgery should be utilized as necessary. Parents should be warned that transient emotional lability and behavior aberrations are not uncommon and that children appear to recover more quickly when the parents adopt a permissive attitude.

**Prevention.** At present, vaccination is available for poliomyelitis and for rabies; in the latter, vaccination is preferably combined initially with rabies antiserum. Vaccines have not proved successful against the arthropod-borne encephalitides in which they have been tried. More success may be expected from control of the arthropod vector by insecticide sprays and repellents. Avoidance of exposure to known animal reservoirs, e.g., mice in the

case of lymphocytic choriomeningitis, is clearly advisable.

### SUBACUTE SCLEROSING LEUKOENCEPHALITIS

Subacute sclerosing leukoencephalitis (van Bogaert) is a progressive illness occurring almost exclusively in children of school age. Although certain features of the disease suggest either a degenerative or an infectious disease of the central nervous system, both the clinical course and the pathologic findings are sufficiently characteristic to warrant its consideration as an entity of unknown etiology.

The initial manifestations are usually those of psychic and intellectual deterioration, diminution of scholastic ability often being an early symptom. Various types of dyskinesias ranging from myoclonic jerks to convulsive episodes occur subsequently. Cachexia and unexplained periods of fever are common. The cerebrospinal fluid frequently reveals a paralytic type of colloidal gold curve and at times a questionable increase in protein, but otherwise it is normal; there is apparently no pleocytosis. Electroencephalography reveals characteristic rhythmic complexes (K waves)

synchronous with but not the result of myoclonic jerks; they may be absent in isolated tracings. Deterioration is progressive, terminating with decerebrate rigidity and complete dementia; death usually occurs within a matter of months.

Pathologically, the disease consists of a diffuse gliosis, usually with relatively little demyelination, accompanied by a chronic inflammatory reaction; the lesions are usually most severe in the subcortical white matter, but the cortex, basal ganglia, thalamus, hypothalamus and spinal cord may also be involved. Intranuclear and intracytoplasmic inclusion bodies have been identified in a number of instances, but attempts to isolate a virus have been unsuccessful to date.

## RICKETTSIAL DISEASES

The rickettsiae are a group of microorganisms which commonly inhabit the alimentary canal of certain insects and may be associated with disease in man. Stained preparations appear under the ordinary microscope as pleomorphic coccobacilli 0.3 to 0.5 micron in diameter. Most species are retained by bacterial filters, and all require the presence of living cells for multiplication. Biologically, the rickettsiae have some of the characteristics of bacteria and some of viruses and are classified in an intermediate position.

The rickettsial diseases of man, with the exception of Q fever, are febrile illnesses with rashes. They may be separated into four groups on the basis of clinical characteristics, insect vectors, etiologic agent and epidemiology (Table 78).

Epidemic typhus and endemic typhus are almost identical clinically and pathologically. The etiologic agents are so similar antigenically that cross reactions occur in Proteus or rickettsial agglutination tests. The two forms of the disease may be distinguished by specific complement fixation tests and by the

inability of epidemic typhus to produce a scrotal reaction in guinea pigs. Brill's disease is a recrudescence of epidemic typhus.

There are many related strains of rickettsiae which cause spotted fever of variable severity in different parts of the world. The list includes boutonneuse fever of the Mediterranean regions, São Paulo, Tobia and pinta fevers of South America, Kenya or Nigeria fever of Africa, and many others. Rickettsial-pox is included in the spotted fever group because of antigenic relationships of *Rickettsia akari* to the etiologic agent of Rocky Mountain spotted fever.

Tsutsugamushi fever, or scrub typhus, was known in certain areas of Japan for many years, but not until the beginning of World War II was it learned that the disease was present also among the populations of India, Australia, the Dutch East Indies, and Malaya. Effective vaccines are not available, and scrub typhus continues to be a real hazard to those who enter endemic areas.

Q fever differs clinically, histologically and epidemiologically from the other diseases

Table 78. Rickettsial Diseases of Man  
(Summary of Pertinent Information)

Group	Disease	Etiologic Agent	Arthropod Vector	Animal Host	<i>Proteus</i> Agglutination*	Geographic Distribution
Typhus.....	Epidemic typhus	<i>R. prowazeki</i>	Body louse	None	OX19	Worldwide; rarely U.S.A.
	Brill's disease	<i>R. prowazeki</i>	None	None	OX19	Eastern coastal cities of U.S.A.; Israel
	Murine typhus	<i>R. mooseri</i>	Rat flea, louse	Rat	OX19	Worldwide; southern states of U.S.A.
Spotted fever...	Rocky Mountain spotted fever	<i>R. rickettsii</i>	Tick	Rodents mammals	Variable OX2 or OX19	North and South America; related diseases worldwide
	Rickettsial-pox	<i>R. akari</i>	Mite	House mice	None	Reported from Eastern U.S.A.
Tsutsugamushi fever.....	Scrub typhus	<i>R. orientalis</i> (tsutsugamushi)	Mite	Rodents	OXK	Far East
Q fever.....	Q fever	<i>R. burneti</i> ( <i>Coxiella burnetii</i> )	? Rarely ticks	Ticks, cattle, sheep, goats	None	Worldwide; western U.S.A.

\* Specific serologic procedures using rickettsial antigens in complement fixation, agglutination or neutralization tests are more reliable.

listed and is classified with them only because it is caused by a rickettsia.

The pathology, methods for making a laboratory diagnosis, and manner of treatment of each of the rickettsial diseases in man are so similar that it seems appropriate to discuss these topics as a whole before describing the individual diseases.

**Pathology.** The pathologic lesion of the arthropod-borne rickettsial diseases is sufficiently distinctive to be diagnostic in patients with a history of an exanthem. The main changes involve the small blood vessels, chiefly of the skin, subcutaneous tissue and central nervous system. The endothelial cells swell, and occlude the small blood vessels, and thrombosis results. The occluded vessels are surrounded by cuffs of mononuclear cells, plasma cells and macrophages. Rickettsiae localize in the endothelium of capillaries and extend via the intima into larger vessels. Rocky Mountain spotted fever may be distinguished histologically from other rickettsial diseases by the presence of rickettsiae in the smooth muscle cells of the media. This produces more severe destruction of blood vessels and may explain the occurrence of necrosis of skin in sites such as the ear lobes, fingers, toes and scrotum.

The symptomatology of vector-transmitted rickettsial diseases correlates with the degree of involvement and the location of affected vessels. For example, the fall in blood pressure, an outstanding clinical feature of rickettsial disease, is generally conceded to be the result of changes in the peripheral vessels. Perivascular reactions in the lung may result in atelectasis and pneumonia. Vascular changes in the brain may produce central nervous system symptoms.

**Q fever,** which is not accompanied by a rash and does not require an insect vector, differs pathologically from the other rickettsial diseases. The major, and usually the only, lesions occur in the lungs, where there is a patchy interstitial pneumonitis with copious exudate composed of fibrin and mononuclear cells. Alveolar walls, alveolar ducts and terminal bronchioles are infiltrated by large mononuclear cells.

**Diagnosis.** The diagnosis of a rickettsial infection in man usually requires laboratory confirmation which is most readily established by demonstration of acquired specific antibodies. In unusual cases when serologic tests are unobtainable or equivocal it may be necessary to identify the etiologic agent.

**Serologic diagnosis.** During studies of the

etiology of typhus fever, Felix isolated a strain of *Proteus vulgaris* from the urine of a patient. This strain (OX19) was not the etiologic agent of typhus, but by coincidence had sufficient antigenic similarity to *Rickettsia prowazeki* so that serum from patients convalescent from typhus fever contained high titers of OX19 agglutinin. Additional strains of *Proteus* related to the etiologic agents of tsutsugamushi (OXK) and Rocky Mountain spotted fever (OX2) were also discovered. The use of these easily prepared antigens in agglutination tests with patients' serums is referred to as the Weil-Felix reaction.

In epidemic typhus fever the agglutination to OX19 usually reaches a titer greater than 1:160 during the second week of illness; the OX2 and OXK titers remain low. The agglutinin pattern observed with murine typhus is similar to that of epidemic typhus, and the two infections cannot be distinguished by this method. The *Proteus* agglutination test is of little value in the diagnosis of Rocky Mountain spotted fever, owing to the variations in the degree and types of response; classically, the patient should develop a high titer of OX2 agglutinins and little, if any, antibody against OX19 and OXK. *Proteus* OXK agglutinin titers are high after Tsutsugamushi disease. Convalescent serum from patients with Q fever or rickettsialpox does not agglutinate to significant titer the *Proteus* strains used in the Weil-Felix reaction. *Proteus* titers do not persist and are usually below a significant level within three months following the illness.

Specific serologic procedures using rickettsial antigens in complement fixation, agglutination or neutralization tests are much more reliable than the Weil-Felix reaction and should be used to confirm the diagnosis of rickettsial infections. Two samples of serum, one obtained during the first week of illness and the other two or three weeks later, should be available to determine whether a significant increase in titer has occurred during the course of the illness.

**Culturing of rickettsiae.** Rickettsiae may be propagated by inoculating susceptible experimental animals or the developing chick embryo. These techniques are seldom required to diagnose rickettsial infections, but may be used, for example, to study the effectiveness of various antibiotics or to detect the presence of rickettsiae in milk, dust or insects.

The guinea pig responds to intraperitoneal inoculation of rickettsiae-containing material

with a sharp elevation of body temperature that persists for several days. The febrile animal may appear ill, but does not have a rash and only infrequently succumbs. Microscopic examination of Macchiavello-stained impression smears made from the spleen reveals many typical rickettsiae. Specific identification of newly isolated strains of rickettsiae may be performed by cross-immunity tests in animals or by serologic techniques.

Rickettsiae grow well in the yolk sac of the developing chick embryo, and, when large amounts of infectious material are required, the egg is the usual source. Chemical and physical methods may be used to prepare purified antigens or vaccines.

The culturing of rickettsiae in the laboratory is extremely hazardous and has been the source of infection for many investigators. This is a task for a special laboratory with proper facilities and immunized personnel. Serologic procedures, using killed antigen and heat-inactivated serums, involve little risk to the laboratory worker.

**Treatment.** Treatment of rickettsial infections is much more effective since the discovery of the broad-spectrum antibiotics. Mortality rates have fallen markedly, the morbidity rate has decreased, and complications have become infrequent. These drugs, however, are not immediately or invariably effective in influencing the course of the disease, and clinical relapses are not uncommon. Rickettsiae have been isolated from the blood of patients who have received presumably adequate doses of an antibiotic. These difficulties are related to the fact that chloramphenicol and the tetracyclines suppress, but do not destroy, the rickettsiae. Final eradication of the microorganism depends upon the immune processes of the host. Intermittent administration of an antibiotic—five days of treatment, five days without drug and then another five days of treatment—has been suggested as the most effective method.

The recommended dose of the tetracyclines or chloramphenicol to children is 50 to 100 mg. per kilogram per day orally in four divided doses. The maximum or adult daily dose is 4 gm. When the intravenous route is used, 30 to 40 mg. per kilogram per day of either drug should be administered in three equal doses.

Early diagnosis and the proper use of antimicrobial agents are all that is necessary in the management of most rickettsial infections. Vigorous supportive therapy, parenteral fluids,

transfusions, sedations and/or oxygen are necessary for the severely ill patient.

Cortisone has been used with an antibiotic in a few instances when the response to the antibiotic alone was not satisfactory. Although the results have been described as excellent, sufficient information is not available to evaluate this therapy critically, and corticoids are not recommended for the average case.

## TYPHUS FEVER

(EPIDEMIC TYPHUS, LOUSE-BORNE TYPHUS)

**History.** Typhus fever has been associated with misery among mankind since man donned clothing. Typhus was probably responsible for the plague of Athens 430 B.C.; it existed during the Middle Ages and was associated with each of the serious famines in England prior to the discovery of America. Typhus was spread through Europe by louse-infected soldiers and was often the most important factor in determining the outcome of battles or the survival of nations.

In more recent years typhus has been an Old World disease with major outbreaks during time of war. In October, 1943, the disease broke out in Naples as the Allied occupation troops arrived. Typhus was encountered in Nazi concentration camps and was spread through Europe by the escaping inmates. Epidemics have occurred among immigrants in coastal cities in America, but typhus has not been common in the United States during recent years. The existence of endemic areas within a few hours of travel distance, however, makes epidemics of typhus in this country a possibility.

**Etiology and Transmission.** Man is the sole reservoir of *Rickettsia prowazeki*, the etiologic agent of epidemic typhus. The body or head louse may become infected by feeding upon the blood of a person with rickettsemia. The ingested organisms multiply within the cells lining the alimentary tract of the insect and are eliminated in the feces.

Contaminated feces may be introduced into a susceptible human host through abrasions or perforations in the skin, or by way of the conjunctival sac or upper respiratory tract. Inhalation of dried, infected louse excreta present in the clothing, bedding or furniture of a typhus patient is probably an important source of typhus infection.

The infected louse dies soon after con-

tracting typhus and seldom has more than a week to spread disease. The louse cannot fly or jump, but may crawl short distances to another human being, especially if his original host becomes uncomfortably hot or cold.

**Clinical Manifestations.** Typhus fever was a much milder disease in children than in adults even before the availability of chemotherapeutic agents. In the 1943 epidemic in Naples, for example, the mortality rate among children was 1.5 per cent compared to 22 per cent in adults.

The clinical manifestations of typhus in children may include fever, transient rash and only few constitutional symptoms, which often make recognition of the disease difficult.

The incubation period is usually less than fourteen days and is followed by an abrupt onset with severe frontal headache, weakness, malaise, generalized aches and pains, chills, and fever of 104° F. or more. Four to seven days later the rash appears.

Faint, rose-colored spots of irregular outline 2 to 4 mm. in size which fade with pressure appear first over the chest and spread gradually over the abdomen, back and extremities. In twenty-four to forty-eight hours the lesions become dark red and no longer fade with pressure. The lesions may spread to include the palms and soles, but the face and scalp usually remain free. Petechial lesions occur in severe cases. The rash remains for a variable period of time; it may be present for only a few hours or persist after the temperature has returned to normal. In general, the more profuse the rash, the more severe is the disease.

The appearance of the rash marks the beginning of the critical period. The temperature remains high and unrelenting, and periods of stupor are interrupted by bouts of violent delirium. The blood pressure is low, and renal output decreased. Oral intake is low and requires parenteral supplementation. In the absence of complications such as pneumonia, severe central nervous system involvement or renal insufficiency, which are frequently fatal, the patient begins to improve during the third week. The temperature gradually falls, the central nervous system symptoms disappear, and the headache ceases. Recovery from typhus is complete, and even in patients with evidence of diffuse involvement sequelae are rare.

**Laboratory Data.** Leukopenia with a relative lymphocytosis early in the disease is usually followed by a leukocytosis during the second and third weeks; a normocytic anemia

is common. Urinary findings vary with the degree of renal involvement; albuminuria and microscopic hematuria are frequent.

**Differential Diagnosis.** Meningococcemia, typhoid, measles or smallpox may be confused with typhus, but the history, clinical course and laboratory data usually permit a proper diagnosis.

**Control Measures.** The immediate destruction of vectors with an insecticide with persisting effect such as DDT is an important measure in the control of an epidemic. Dust containing excreta from infected lice is also capable of transmitting typhus, and care must be taken to prevent its inhalation. This usually requires washing the patient's clothing, bedding and other possessions with hot water and a disinfectant after they have been dusted with DDT. Vaccination of persons likely to come in contact with typhus is recommended. The preferred vaccine is a killed preparation of a rickettsia grown in the yolk sac of the chick embryo. Insufficient data are available concerning differences in sensitivity to broad-spectrum antibiotics by strains of rickettsiae, but, if resistant forms do not occur, the administration of an antibiotic may be adequate prophylaxis for brief exposures to typhus.

**Treatment.** See page 555.

## MURINE TYPHUS

**Etiology and Transmission.** Unlike epidemic typhus, which is not seen among children in the United States, endemic or murine typhus is fairly common, particularly in Texas and the southeastern states, and has been seen in most regions of this country. It usually occurs in the summer and fall in contrast to typhus, which is characteristically a disease of winter and spring.

Endemic or murine typhus is a disease of rats caused by *Rickettsia mooseri*. It is usually transmitted from rat to rat by the rat louse or flea. In both the rat and the insect vectors murine typhus is a mild disease with no apparent effect on their life span. The eggs laid by infected fleas or lice do not transmit *R. mooseri* to the next generation. Man usually acquires murine typhus when bitten by an infected rat flea, but can also be infected by inhaling or possibly ingesting infected excreta of fleas.

**Clinical Manifestations.** Murine typhus is a mild, seldom fatal illness that can be distinguished from epidemic typhus only by special laboratory procedures.

The incubation period is usually about eight days. Prodromal symptoms such as headache, arthralgia and backache are followed by a gradually increasing temperature which may reach 106° F. in children and last nine to fourteen days. On the first to the eighth day of fever, most often by the fifth day, the rash appears. As in typhus, the eruption begins on the trunk and spreads to the periphery, rarely involving the face, palms or soles. Initially the skin lesion is a dull red macule with ill-defined margins which becomes slightly papular as it matures. It never becomes purpuric and persists for a much shorter period than the rash of epidemic typhus. Twenty per cent or more of children may have no rash or such a transient one that it is not noted. Central nervous system symptoms are uncommon, as is peripheral vascular collapse or other complications.

**Control Measures.** Control of murine typhus requires elimination of the rat reservoir or the insect vector, or both. Immunization of personnel in contact with possibly infected rats is recommended. The vaccine is different from that used for epidemic typhus, although most persons who have recovered from one form of typhus are also immune to the other.

**Treatment.** See page 555.

## BRILL'S DISEASE

Brill's disease is an unusual phenomenon in which a patient with a history of typhus suffers a recrudescence of his illness. It has been observed among immigrants from eastern Europe in the coastal cities of the United States and more recently in Israel. The strains of rickettsiae isolated from such patients are indistinguishable from those of epidemic typhus. It is presumed that organisms have persisted in the tissues of the host for years, and then, for reasons not understood, they increase in number and produce clinical symptoms. A patient with Brill's disease can infect lice and is a potential point of origin for a typhus epidemic when the vector is present. Brill's disease is not a problem in children.

## SCRUB TYPHUS

(TSUTSUGAMUSHI FEVER, MITE TYPHUS)

Scrub typhus, or tsutsugamushi fever, has been recognized in Japan and Formosa for centuries, but not until World War II was

it realized that this disease could be found in localities stretching from India to the Philippines, including Burma, Malaya, New Guinea, the Solomon Islands and Queensland. The incidence of scrub typhus among United States Army personnel in bases north of Australia during 1942 and 1943 was about ten per 1000 troops per year with a case fatality rate of 3 to 10 per cent.

**Etiology and Transmission.** *Rickettsia tsutsugamushi*, also known as *R. orientalis*, is the causal agent of scrub typhus. The vectors which carry the agent are the larval forms of the "chigger" or trombiculid mites. The larvae feed on rats or other rodents and when not feeding are present on low-lying vegetation from where they can attack man. *Rickettsia tsutsugamushi* has been isolated from many species of rodents, and it seems likely that both mites and rodents can serve as reservoirs of rickettsia.

Scrub typhus is mainly a disease of persons whose occupations bring them into contact with infected mites.

**Clinical Manifestations.** The symptomatology of scrub typhus, although showing several distinctive features, is remarkably similar to that of other rickettsial infections. The disease may vary in severity, but characteristically has an abrupt onset twelve to eighteen days following the bite by the infected mite. The initial symptoms are fever and headache, sometimes accompanied by anorexia and vomiting.

Some form of skin lesion is usually present at the site of the mite bite, which begins as an asymptomatic, pink papule, increases in size and becomes either an eschar, consisting of a central, black scab 4 to 8 mm. in diameter surrounded by a dull, red areola, or, in moist areas (axilla, perineum), a pinched-out shallow ulcer. By the end of the first week of illness a maculopapular rash develops on the chest and abdomen and gradually spreads to involve the entire body, except usually the hands and face. Diffuse, tender adenopathy, more marked in the region of the primary lesion, is a common part of the clinical syndrome.

Laboratory confirmation may be obtained by isolation in mice of the causative agent. The Weil-Felix reaction for *Proteus* OXK may become positive by the third week of the illness, but is not invariable, especially in patients treated with antibiotics.

In severe cases signs of pulmonary or cardiac involvement may develop during the second week of illness, and death results.

In mild or treated cases improvement begins by the end of the second week, fever decreases, the rash fades, and the eschar heals. The mortality rate, when antibiotics are used, is less than 5 per cent.

**Control Measures.** The difficulties encountered in attempting to eliminate the widely prevalent mite vector of scrub typhus have led to investigations of control by vaccines. Unfortunately, the vaccines tested have not proved entirely satisfactory, owing to the many antigenically different strains of *R. tsutsugamushi* which are pathogenic for man. It is hoped that an effective polyvalent vaccine can be prepared. Until such a time, protective clothing and early treatment with broad-spectrum antibiotics are the most useful aids to prevent death from scrub typhus.

## ROCKY MOUNTAIN SPOTTED FEVER

**History.** Rocky Mountain spotted fever is an exanthem of man first recognized in the Rocky Mountain region of the United States by Maxey in 1899. Ricketts inoculated monkeys and guinea pigs with infected human blood and was able to transmit the infection and demonstrate the causative agent. He later showed that the disease is spread by the wood tick and discovered infected ticks in the Bitter Root valley of Montana. The name "Rocky Mountain spotted fever" gives a false impression of geographic limitation to a disease that has been observed throughout the United States. The attack rate in Virginia, Delaware and Maryland, for example, is as high as or higher than that in Nevada, Idaho and Montana.

**Etiology and Transmission.** The etiologic agent of Rocky Mountain spotted fever, *Rickettsia rickettsii*, is maintained in nature

by many hosts, including the ground squirrel, jack rabbit, chipmunk, wood rat, meadow mouse and weasel; the animal hosts do not become ill. Transmission among animals and from animal to man is most commonly achieved through the wood tick, *Dermacentor andersoni*, or the dog tick, *Dermacentor variabilis*.

Shepherders, hunters, woodsmen or others whose occupation or recreation brings them into the isolated tick-infested woods of Montana or Idaho are most likely to be bitten by an infected wood tick. In the eastern United States, however, more infections occur in children and women who are probably bitten by infected dog ticks encountered during outings in the woods or while handling the family dog.

Infected female ticks may pass rickettsiae through eggs to the progeny and thus maintain a reservoir for a long time without infecting man.

**Clinical Manifestations.** The incubation period in children varies from one to eight days. The disease usually begins with such nonspecific symptoms as headache, fever, anorexia and restlessness. There is a history of tick bite in approximately half the reported cases, but local reaction at the site of the tick bite is uncommon. The discrete, pale, rose-red macules or maculopapules appear one to five days after the onset of illness. The rash characteristically begins peripherally on the ankles, wrists or lower legs and then spreads, often rapidly, to involve the entire body, including the scalp, palms and soles. Early, the rash fades with pressure, but after one or two days it becomes more purple and no longer disappears with pressure. The clinical illness is similar to that of typhus. Bizarre central nervous system symptoms, peripheral circulatory collapse,

FIG. 166. Patient with Rocky Mountain spotted fever. Note the pronounced edema with closure of the eyes. (Courtesy of Dr. Weston Kelsey, Winston-Salem.)

FIG. 167. Eleventh day of rash in severe Rocky Mountain spotted fever. Note the hemorrhagic character of the diffuse rash. (Courtesy of Dr. Weston Kelsey, Winston-Salem.)

electrolyte disturbances and pneumonia are the most common complications. Fatality rates among unvaccinated children before the availability of antibiotics varied from 10 to 40 per cent. It is generally accepted that rickettsial strains of high and low virulence exist throughout the United States. Recovery in uncomplicated cases occurs in the third week, initiated by a fall in temperature and gradual subsidence of symptoms.

The clinical laboratory findings are not specific.

**Control Measures.** The reservoirs and vectors of spotted fever are so numerous and widespread that removal of the source of infection is not feasible. Protection from tick bite is best accomplished by the use of proper wearing apparel plus tick repellents or, optimally, the avoidance during the tick season of areas known to be infested.

Ticks rarely transmit infection until they have fed on the person for several hours; thus careful examination of children who have been playing in the woods and prompt removal of ticks may prevent disease. This is best accomplished by the use of gloves or forceps which will protect the operator from becoming infected by the crushed insect. The use of a hot match head or a coating of petrolatum to provoke the tick to remove his mouth parts is often recommended.

Vaccines are available and should be used

by those whose pursuits require unusual exposure to virulent strains of rickettsiae.

**Treatment.** See page 555.

## FIÈVRE BOUTONNEUSE

Fièvre boutonneuse is a relatively benign rickettsial disease, limited almost exclusively to Europeans in the countries surrounding the Mediterranean. The natives in this area are apparently infected early in life and develop long-lasting immunity. *Rickettsia conorii*, the causal agent, is transmitted by the dog tick, *Rhipicephalus sanguineus*. As in rickettsialpox or scrub typhus, a local lesion known as *tâche noire*, or primary eschar, develops, and this is followed by a diffuse, maculopapular rash which later becomes petechial. Severe systemic manifestations are uncommon. The diagnosis is usually made on the basis of the clinical symptoms in an exposed person with a primary skin lesion. Agglutinins to both OX19 and OX2 occur during the second week of the disease and may be used to confirm the diagnosis if the more specific complement fixation test is not available. Treatment with broad-spectrum antibiotics is followed by rapid clinical improvement.

## RICKETTSIALPOX

**History.** In 1946 an epidemic of an unusual febrile disease with varicelliform rash occurred in a New York housing development. The disease was recognized as a new entity caused by a previously unknown rickettsia, *Rickettsia akari*, and transmitted by the mouse mite, *Allodermamyssus sanguineus*. The illness, named rickettsialpox, has continued endemic in New York, and isolated cases have been reported from Boston, Philadelphia and Cleveland. The mite vector has been found in many cities of the United States, and more widespread distribution of rickettsialpox may be anticipated.

**Clinical Manifestations.** Rickettsialpox is a mild illness characterized by an initial skin lesion followed by fever, chills, headache and a papulovesicular rash.

The initial lesion, presumed to be the site of the mite bite, has been observed in more than 90 per cent of cases. It may be located anywhere on the body, beginning as a non-tender, nonitching, firm, red papule, 0.5 to 2.0 cm. in diameter. A deeply entrenched vesicle develops in the center of the papule and ruptures after several days, leaving a

crusted, pigmented lesion or eschar which may persist three weeks or longer. Adjacent lymph nodes become enlarged and tender, but do not suppurate.

The initial lesion is followed in two to seven days by fever, headache, chills and sweats. Temperature varies between 102° and 105° F., but the patient remains oriented and does not appear severely ill.

Within twenty-four to seventy-two hours after the onset of fever scattered erythematous maculopapules appear over the body, showing no preference for trunk, head or extremity. The lesions enlarge, become more papular and develop vesicles on the summit of each papule. The secondary lesions (rash) resemble the initial lesion except that they are smaller in size and heal without leaving scars in four to seven days.

The duration seldom exceeds seven to ten days. Complications, sequelae and fatalities are rare.

Except for leukopenia with relative lymphocytosis early in the disease, studies of blood, urine or stool of patients with rickettsialpox show no characteristic changes.

**Differential Diagnosis.** The rash of rickettsialpox may be confused with that of chickenpox. In varicella, however, the vesicles are superficial, thin, dewdrop lesions which appear in successive crops beginning on the chest. These differ from the deeply seated, randomly distributed firm vesicles of the rickettsial disease. The initial lesion, the presence of fever before the rash and a history of chills may also help in the differentiation. Other diseases to be considered include infectious mononucleosis, meningococcemia, Rocky Mountain spotted fever and typhus.

**Control Measures.** Preventive measures should include the eradication of rodent reservoirs as well as the mite vector. *Rickettsia akari* grows well in the yolk sac of the developing chick embryo, and a vaccine could be prepared if there were substantial need.

**Treatment.** See page 555.

## Q FEVER

**History.** Q fever, a febrile disease without rash and often associated with an interstitial pneumonia, was originally observed among Australian abattoir workers in 1935. Initially the disease was infrequently diagnosed in this country except among laboratory workers. During World War II epidemics of "pneumonia of unknown etiology" and "Balkan

grippe" occurring among military personnel in the Mediterranean theatre were shown to be Q fever. Since that time the disease has been reported from all parts of the world.

**Etiology and Transmission.** Q fever occurs naturally in cattle, sheep, goats and many wild animals. The causative agent of Q fever, termed either *Rickettsia burneti* or *Coxiella burnetii*, has been found in many species of ticks, in which it may pass from the adult through ova to progeny.

Experimentally, Q fever has been transmitted by insect vectors through the skin and by inhalation. Careful studies of outbreaks of the disease in human beings have failed to incriminate insect vectors, although this mode of transmission may be important among animals. Person-to-person spread, if it occurs, is rare. Q fever epidemics observed in Italy during the war remained localized and involved only the inhabitants of specific quarters, a fact which led to the idea that Q fever was a "place infection." Recent studies suggest that excreta from infected animals or insects may be a source of infection. In the endemic areas of California, human infections are related to contact with animals which show evidence of *R. burneti* infection. In northern California sheep are the probable source of infection; in southern California, the dairy cow. The main route of infection appears to be inhalation of contaminated material from domestic animals or by direct exposure or by contact with wool, hides, hay or other contaminated materials.

Milk may be another source of infection for man. In a study of sporadic cases of Q fever in England, Marmion isolated *R. burneti* from ten of the twenty (raw) milk sources used by the patients; *R. burneti* may survive pasteurization temperatures.

**Clinical Manifestations.** Q fever may be a mild disease diagnosed only in retrospect by serologic survey, but, as commonly recognized, it is a disease of moderate severity with a duration in children of two to three weeks. The onset of illness is characteristically sudden, but in some instances symptoms may increase slowly in intensity. Malaise, fever, chilliness and generalized weakness appear early, but the most prominent symptom is severe frontal headache, often associated with pain upon movement of the eyes. There is no rash. Complaints referable to the respiratory tract are mild and infrequent. Cough may occur late in the first week of illness with production of small amounts of blood-streaked sputum, and

chest pain may be associated with pneumonitis or infrequently with pleural effusion.

Pneumonitis is common; rales may be audible, but the diagnosis of pulmonary involvement is usually established roentgenographically. Pulmonary consolidation is usually patchy and in the peripheries of the lower lobes; hilar involvement is rare. Resolution is slow and may require three to six weeks.

During the acute phase the temperature may reach 104° to 105° F., but may be remitting with wide daily swings. After five to fifteen days the temperature gradually returns to normal, and most symptoms disappear. After severe illness convalescence may be prolonged for several weeks. Complications are rare. The mortality rate is less than 1 per cent.

Routine hematologic data are not significant. Falsely positive serologic tests for syphilis may exist during the illness.

**Control Measures.** Complete control of Q fever is not possible because of ignorance of the exact mode of spread. Recognition of the disease in livestock should alert communities to the risk of infection. Stockyard workers and others exposed to infected material might receive the formalinized vaccine, which at present is not generally available. Milk from infected herds must be pasteurized at temperatures sufficient to destroy the rickettsiae. Person-to-person spread of Q fever is not a problem, and special isolation measures are not necessary.

**Treatment.** See page 555.

# MYCOTIC INFECTIONS

## ACTINOMYCOSIS

**Definition and Etiology.** Actinomycosis is a chronic granulomatous infection characterized by the formation, in various parts of the body, of abscesses which tend to break down and form multiple draining sinuses. The disease is more frequent in adults than in children, but must be considered in the differential diagnosis of chronic infections of the lung and of draining sinuses in the jaw, neck or thoracic or abdominal region.

The causative agent, the anaerobic *Actinomyces (bovis) israeli*, appears in the lesion as small hyaline-like to yellow "sulfur granules." On microscopic examination the crushed granule is seen to be a mass of entangled branched mycelial filaments of approximately the same width as bacteria. The filaments in the periphery of the granule may be clubbed. The organisms must be cultured anaerobically, preferably in thioglycolate broth or brain-heart infusion agar. They can often be recovered from the mouth, from tonsils and from pyorrheal pus of patients without actinomycosis, suggesting the possibility of an endogenous source of infection. The disease is not contagious.

**Pathology.** The lesions are those of a chronic granulomatous infection with a great tendency to suppuration with abscess formation, fibrosis, the formation of scars and multiple draining sinuses. The presence of typical "sulfur granules" is characteristic but not pathognomonic.

**Clinical Forms.** *Cervicofacial actinomycosis* (57 per cent of cases). The fungus enters through a carious tooth or the mucous membrane of the mouth or pharynx and produces a gradually enlarging hard or "woody" swelling in the jaw or neck. The tense overlying skin is often reddish or purple. The swelling later softens and drains to the outside through multiple sinuses, but can penetrate deeper to involve the bone and meninges. "Sulfur granules" may be found in the discharging pus. Pain is minimal, and the general health is not greatly affected.

*Abdominal actinomycosis* (22 per cent of cases). Infection may follow an appendectomy and may appear several months later as a hard, irregular mass in the ileocecal region. This mass tends to soften and drain to the outside. Frequently, however, the

infection extends through the diaphragm, after involving the liver and other abdominal organs, to produce thoracic lesions. With a severe infection there are chills, fever, night sweats and loss of weight.

*Thoracic actinomycosis* (15 per cent of cases). The clinical pattern is that of a chronic pulmonary infection with cough, sputum, fever, dyspnea, hemoptysis and loss of weight. Roentgenograms generally reveal bilateral involvement, usually in the lower lobe. The infiltration is often smooth and massive. Extension to the pleura causes accumulation of pleural fluid and involvement of the ribs and subcutaneous tissues with multiple sinus formation.

**Diagnosis.** The diagnosis requires finding the organisms in the pus or biopsy material from the sinus walls. A drop of pus is crushed under a coverglass and examined under the low power of the microscope for the typical "sulfur granules." The disease closely simulates tuberculosis, but other diseases which must be considered are osteomyelitis, amebiasis, hepatic abscess, chronic appendicitis, pulmonary abscess and other fungus infections.

**Prognosis.** This depends upon the extent of the infection; widespread infection may be fatal.

**Prevention and Treatment.** Removal of chronically infected tonsils and treatment of pyorrhea may eliminate possible sources of infection. A general supportive regimen similar to that used in the treatment of tuberculosis should be supplemented by penicillin therapy alone or in combination with sulfadiazine. Potassium iodide is useful in chronic actinomycosis and should be given with the more specific drugs for three to six months after the patient is apparently well. Surgical excision and drainage may be necessary. The broad-spectrum antibiotics or stilbamidine are no more effective than penicillin combined with a sulfonamide; they can be used, alternating with penicillin if the patient fails to respond to the initial therapy, but failure to respond generally means inadequate surgical drainage.

## NORTH AMERICAN BLASTOMYCOSIS

**Definition and Etiology.** North American blastomycosis is an infection with *Blasto-*

*myces dermatitidis* characterized by chronic granulomatous lesions and micro-abscess formation in any part of the body, but with a predilection for lungs, skin and bone. It is practically confined to the North American continent and especially to the Southeast and Mississippi Valley states. Recent evidence suggests that the usual portal of entry is the lungs and that both skin and bone lesions are metastatic.

The source of the infection is unknown. *Blastomyces* have been found in domestic animals (dog and horse) but not living free in nature (soil and wood). In tissues and in pus the fungus appears as a thick-walled, double-contoured, single-budding organism averaging 8 to 12 microns in diameter. On Sabouraud's medium at room temperature it grows slowly as a mold composed of branching filaments and small spores. The budding yeastlike forms are obtained on blood agar incubated at 37° C. Small forms of the organism must be distinguished by cultural means from *Histoplasma* and *Monilia*. The disease is not spread from man to man.

**Pathology.** The organism incites an inflammatory reaction which in the acute phase and in the advancing portions of the lesion is characterized by the formation of minute (micro-) abscesses, in which a search should be made for the organisms. In the older portions of the lesion the reaction is essentially chronic and granulomatous, resembling tuberculosis. Necrosis and fibrosis are present to a variable degree.

**Clinical Forms.** Evidence is accumulating that the disease, like coccidioidomycosis and histoplasmosis, may exist more frequently as a mild primary infection than as the more severe form usually recognized at present. In a well documented epidemic seven of ten patients were children, and the majority of these had only mild pulmonary lesions and few systemic manifestations; one patient cleared spontaneously without therapy.

**Pulmonary blastomycosis.** The usual history is of an acute upper respiratory infection which persists. Cough, chest pain, weakness and loss of weight may occur. The roentgenogram may show a variety of lesions; infiltrations resembling virus pneumonia, diffuse miliary lesions, nodular or homogeneous areas of consolidation and abscesses of various size. With progression, the symptoms increase in severity and the patient loses weight, has irregular bouts of fever, has bloody, purulent sputum and becomes cachec-

tic. Spread of this infection may be either local or hematogenous.

**Cutaneous blastomycosis.** Cutaneous blastomycosis may result by direct inoculation of the organism into the skin or by dissemination to the subcutaneous tissue from a pulmonary lesion which may be unrecognized. The initial lesion is a small papule, usually on an exposed area of the body, which undergoes ulceration and crusting. The infection spreads by peripheral extension with a tendency to heal in the center. The periphery of the lesion tends to be serpiginous with a raised, ulcerated granulomatous border in which there are many micro-abscesses. The pus expressed from the micro-abscesses usually shows the budding organisms. The lesions may be single or multiple, but rarely are there any systemic symptoms unless there is involvement of other organs.

**Disseminate blastomycosis.** The usual sequence is extension from a primary lesion in the lungs to many organs in the body, in particular to the bones, skin, subcutaneous tissues and internal organs. Skeletal involvement results in localized or diffuse osteomyelitis with destruction of bone and the formation of cutaneous sinuses from which pus exudes. The subcutaneous nodules and abscesses, which may be painful, have a tendency to break through the skin and then assume the characteristics of the cutaneous lesions. Systemic symptoms may be relatively mild in the predominantly osteomyelitic form, but severe in the widely disseminated group.

**Diagnosis.** The pulmonary lesions may resemble those of tuberculosis, neoplasms, pneumonia, abscess, sarcoidosis and other fungus diseases. Diagnosis may be made by finding and culturing the organism's in sputum or, in children, in the gastric washings. Pus from draining sinuses should be mixed with a drop of 10 per cent potassium hydroxide and examined for the characteristic refractile, thick, double-contoured, walled organisms. The cutaneous lesions can be mistaken for syphilis, tuberculosis, pyoderma, cat-scratch disease, carcinoma, bromide rashes, granulomas, and other fungus infections.

Infection results in a positive delayed skin reaction to blastomycin or *blastomyces* vaccine. However, a negative skin reaction does not exclude the diagnosis, and a positive reaction may be obtained in persons without clinical manifestations. Severe and disseminate lesions tend to produce complement-fixing antibodies in the blood.

**Prognosis.** The localized, mild pulmonary lesions have a good prognosis, as do the localized cutaneous lesions. Widespread pulmonary and disseminate lesions have a poor prognosis and are usually fatal without extensive treatment. A negative skin test with a positive complement fixation test indicates a poor prognosis and the probability of relapse after therapy. A positive skin test with a negative complement fixation test is a good prognostic sign.

**Treatment.** Hydroxystilbamidine diisethionate is the drug of choice. The initial dose for adults is 50 to 100 mg. given intravenously in 100 ml. of 5 per cent glucose. It is followed by daily intravenous doses of 225 mg. in 300 cc. of 5 per cent glucose for thirty days, or in several series of ten to fourteen days each with a rest period between each series. Proportionately smaller amounts are given to children; weakness, nausea and circulatory collapse may result from too rapid administration. Hydroxystilbamidine is stored in the tissues and continues to exert its effect for months after the course has been completed. When the stilbamidines are not effective, or there is a relapse after several courses, Amphotericin B may be tried. In addition, iodides may be used, but the patient should first be desensitized to blastomycetes vaccine if the skin test is strongly positive. Operation, performed under a mistaken diagnosis of neoplasm, has occasionally been curative in localized pulmonary lesions, but may precipitate dissemination. Appropriate antimicrobial agents should be used for secondary infection occurring in the skin, lungs or bones.

## CRYPTOCOCCOSIS

(TORULOSIS)

**Definition and Etiology.** Cryptococcosis is a subacute or chronic infection caused by *Cryptococcus neoformans* (*Torula histolytica*), a fungus which can invade the lungs, skin, joints and subcutaneous tissues, but has a predilection for the central nervous system. The disease is worldwide in distribution and occurs at all ages. The organism has been found on various fruits, in soil, pigeon excreta and in cow's milk. It probably enters the body through the respiratory tract, but may also enter through the skin.

**Pathology.** The fungus is relatively inert, and the early lesion is a cystlike cavity containing gelatinous material with little or no

cellular reaction. Older lesions may become granulomatous, but cryptococcosis usually remains a nonsuppurative disease. The earliest pulmonary lesion is probably a subpleural nodule which may go on to spontaneous healing. In the brain and meninges there is a chronic inflammatory reaction with giant cells, macrophages and lymphocytes, but relatively few neutrophils.

**Clinical Manifestations.** Symptoms of central nervous system cryptococcosis are those of meningitis or brain abscess, with headache, dizziness and stiffness of the neck. Signs of increased intracranial pressure appear after weeks or months; the cerebrospinal fluid pressure is increased, and the cell count may be high. Coma ensues, and death results from respiratory failure.

The clinical picture of pulmonary cryptococcosis is not diagnostic. There is low grade fever, mild cough, and infiltrative lesions of variable size in the lungs, frequently bilateral. Although pulmonary involvement in itself may cause death, the chief danger is dissemination to the central nervous system.

Infection of the skin usually occurs on the face, beginning as an acneiform, firm, nodular, painless eruption which may enlarge, become necrotic and ulcerate. The lesions resemble carcinoma, sarcoid, tuberculosis and other fungus infections.

Of particular interest is the generalized disseminate form which has been found in the *newborn*. The symptoms date from birth and include central nervous system manifestations, jaundice, hepatomegaly, splenomegaly, chorioretinitis and intracranial calcifications. Hydrocephalus and cerebral degeneration may occur. The manifestations resemble those of congenital toxoplasmosis and cytomegalic inclusion disease.

Infection with cryptococcosis and dissemination of the disease probably depend largely on host factors. There is a great susceptibility in patients with malignant lymphoma, Hodgkin's disease and leukemia; one third of all cryptococcosis occurs in conjunction with these diseases.

**Diagnosis.** Diagnosis is established by finding encapsulated budding yeast cells in the cerebrospinal fluid and in lesions (biopsy) by direct examination and culture. The fungus appears as a thin-walled budding yeast surrounded by a large gelatinous capsule. Growth on Sabouraud's medium is creamy white, mucoid and glistening. Smears from the culture show budding yeast cells,

but the capsule is demonstrated best in a fresh India ink preparation. Fungus cells in cerebrospinal fluid may easily be mistaken for lymphocytes unless the India ink preparation is used to demonstrate the capsule.

In differential diagnosis, tuberculosis and infections by other fungi must be considered.

**Prognosis and Prevention.** The prognosis is serious in all forms of the disease, and meningitis is usually fatal. Early treatment of pulmonary, cutaneous and subcutaneous infections is advisable to obviate the danger of central nervous system involvement. The disease is not communicable from man to man.

**Treatment.** Treatment of localized lesions consists in surgical excision and drainage. Iodides may be helpful. More recently, promising results even in the treatment of cryptococcosis meningitis have been reported from the use of Amphotericin B; other antibiotics are valueless. Sulfonamides have a slight effect.

## MUCORMYCOSIS

**Definition and Etiology.** Mucormycosis is a bizarre, usually acutely fatal disease characterized by a necrotizing and inflammatory process in which broad, nonseptate, hyphal strands can be seen in histologic sections. The causative organisms belong to the family *Mucoraceae*, and two species of the genus *Rhizopus* have been isolated from clinical cases. These organisms are generally saprophytes of widespread distribution (bread molds) and achieve pathogenic invasiveness only in persons whose resistance has been lowered by diabetes or some debilitating illness. The organisms grow well on Sabouraud's medium at room temperature as a true fungus with characteristic asexual and sexual spores.

**Pathology.** When pathogenic and invasive rather than saprophytic, the organism causes an intense inflammatory reaction with a polymorphonuclear response and extensive necrosis. Of particular interest is the tendency of the organism to invade blood vessels and cause thrombosis. The hyphae penetrate and grow in the walls of both arteries and veins, breaking out in some sections through the adventitia and in other parts rupturing the intima. Thrombosis occurs, and the organisms can be seen together with many leukocytes and fibrin strands in the clot. The resulting infarction accounts for much of the necrosis. In addition there may be a

striking invasion of nerves and perineural lymphatics. Involvement of the cranial cavity ("cerebral mucormycosis") may cause leptomeningitis, infarctions due to vascular thromboses, direct nerve involvement by invasion and acute necrotizing encephalitis.

**Clinical Forms.** The disease usually develops in association with severe and prolonged metabolic disturbance through uncontrolled diabetes, uremia, chronic diarrhea, adrenal hormone therapy, prolonged chemotherapy, malignancies and other cachectic states.

**Pulmonary form.** Pulmonary mucormycosis occurs by direct or hematogenous invasion of the lungs resulting in the pathologic processes described above. The clinical picture is that of an extremely acute, severe, lobular pneumonia or infarction. The patient complains of chest pain and has bloody sputum, friction rub, fever and leukocytosis.

**Cerebral mucormycosis.** In this type the organism probably enters the nasal cavity or the sinuses. Necrosis and acute inflammation extend to the orbit, palate, meninges and brain. Symptoms and signs of orbital cellulitis, sinusitis, cavernous sinus thrombosis, nerve involvement or meningoencephalitis result. Of the known cases all except two have been fatal.

**Other forms.** The organism may invade the digestive tract, the heart and other organs, where the same pathologic sequence is observed. Symptoms are those of inflammation and infarction of the involved organs.

**Diagnosis.** The appearance of manifestations of acute inflammation, infarction or necrosis in the lungs, gastrointestinal tract, orbits and the intracranial cavity in a patient debilitated by a chronic disease should suggest the possibility of mucormycosis. Diagnosis depends upon recognition of the fungus in specimens of tissue or of body fluids.

**Prevention and Treatment.** Both prevention and treatment are best accomplished by proper care of the underlying predisposing debilitating illness. The two known recoveries were in diabetic patients whose diabetes was brought under control and the mucormycosis was treated by desensitization with a vaccine made from the fungus, administration of large doses of iodides and antimicrobial treatment of secondary bacterial infections.

## NOCARDIOSIS

**Definition and Etiology.** Nocardiosis is

a noncontagious, subacute or chronic suppurative disease primarily of the lungs, but with a tendency to hematogenous dissemination. The causative organisms belong to the same family as does *Actinomyces*. They are gram-positive with branching filaments, but, in contrast to *Actinomyces*, may be partially or strongly acid-fast, can be grown aerobically on simple media at room temperature and are found living free in nature (soil). Of the nine recognized species, *N. asteroides* is the commonest cause of systemic infection.

**Pathology.** The basic histologic lesion is a focal area of necrosis surrounded by a variable cellular infiltrate. These abscesses are characteristically not encapsulated, but may show secondary fibrosis, or they may caseate and cavitate. Pulmonary infection (probably produced by inhalation of contaminated dust) begins as an acute pneumonitis which may become chronic and persist for a long time. The lesions may extend locally and spread hematogenously to the subcutaneous tissues and to other organs, especially the brain. Demonstration of the organisms in tissues requires the gram or acid-fast technique, since they are not stained by the routine hematoxylin-eosin method. Differentiation from tuberculosis may be extremely difficult because of the histology, the acid-fastness of the organisms and their ready fragmentation into bacillary forms.

**Clinical Forms.** Aside from the localized primary cutaneous and subcutaneous infections which are uncommon in the United States, the clinical picture of nocardiosis is that of a chronic suppurative pulmonary disease which spreads locally and metastasizes to other organs. Twelve per cent of these cases have occurred in children—as early as four weeks of age. Common manifestations are cough, fever, anorexia, weight loss, malaise, night sweats, fatigue, dyspnea, chest pain and leukocytosis up to 50,000 per cubic millimeter. Local extension may result in empyema. A characteristic sequence is pulmonary disease followed shortly by pustular eruption of the skin. There is a pronounced tendency to chronicity with remissions and exacerbations over many years. Secondary intracranial involvement results in cerebral abscess and/or meningitis. When the organisms, particularly *Nocardia madurae*, gain entrance through abrasions in the feet, they produce a burrowing infection of the subcutaneous tissues and bone, *mycetoma pedis*.

**Diagnosis.** Roentgenograms of the lungs usually reveal small infiltrative lesions or

large lobular areas of consolidation, with the lower lobes of the lungs involved most often. Suppuration and cavitation may occur. The important features are chronicity with gradual progression, multiple lesions, failure to show resolution with antibiotic therapy and the diagnosis not established by routine methods.

Differentiation must be made from actinomycosis by cultural means and by examination of the pus (sulfur granules are seldom present in *N. asteroides* infections). This is important, since therapy is different in the two conditions. Owing to the clinical resemblance to tuberculosis and the acid-fastness of the organisms, the differentiation is extremely difficult; it has been estimated that nocardiosis accounts for 1 to 5 per cent of patients in tuberculosis hospitals. When the lesion metastasizes to other organs, the resemblance to staphylococcal pyemia is striking. The chronic pulmonary disease has been also mistaken for cystic fibrosis of the pancreas.

**Prognosis and Treatment.** The over-all mortality is probably over 50 per cent. However, lesions respond well to symptomatic care and sulfonamide therapy in their early stage. Surgical excision may be necessary. The organisms are partially susceptible to the broad-spectrum antibiotics, but resistant to penicillin, in contrast to actinomycosis, in which the organisms are more sensitive to penicillin and other antibiotics than to sulfonamides.

## SPOROTRICHOSIS

**Etiology.** Sporotrichosis is caused by *Sporotrichum schenckii*, a fungus which most frequently infects the skin and subcutaneous tissues, producing a series of nodules and ulcerations. The fungus also may infect the mucous membranes, lungs and other organs. It is one of the most common "deep mycoses" and is the least serious, since it responds well to therapy. The organism has been isolated from soil, plants and infected timber. It is probably inoculated by direct contact into abrasions in the skin.

**Pathology.** Section of a nodule usually shows granulation tissue with epithelioid cells and giant cells surrounding a necrotic area, a lesion similar to that produced by tuberculosis or other fungus infections.

**Clinical Manifestations.** The lesion begins usually in the skin or in the subcutaneous tissue as a small, hard nodule not attached to the skin. This nodule later adheres to

the overlying skin, which becomes darker in color and finally ulcerates, discharging a small amount of purulent material. This primary "chancre" may persist for months and is followed usually by a succession of freely movable nodules, which form a chain along the course of the lymphatic drainage. These nodules may subsequently become attached to the skin and ulcerate. The patient is afebrile, and the general health is not affected. Sporotrichotic infections of the mucous membranes, lungs, bones and other organs occur, but are rare except for bone and joint infections, which comprise 17 per cent of total infections.

**Diagnosis.** The disease may resemble tuberculosis, syphilis or infections by other fungi. The local lesions suggest tularemia, but the general symptoms are not those of an acute bacterial infection. Diagnosis depends upon culturing the fungus from the chancre or subcutaneous nodule.

The fungi occur in the lesions as intracellular, small "cigar-shaped" bodies, 3 to 4 microns in length, and are demonstrated with difficulty. Direct smears cannot be depended upon as a diagnostic procedure. On Sabouraud's medium the fungus grows as a white or black mold identified as clusters of small, delicate, pear-shaped spores borne on short branches of narrow mycelial filaments.

**Prognosis.** Though the disease may persist for many months, the prognosis is good under adequate therapy.

**Treatment.** Oral administration of potassium iodide in increasing amounts up to tolerance is almost specific. The medication should be continued for at least a month after healing has occurred. Abscesses may be aspirated, but incision and curettage should be avoided. For patients who are sensitive to iodides or have systemic lesions, hydroxystilbamidine diisethionate and possibly Amphotericin B may be helpful.

## HISTOPLASMOSIS

Histoplasmosis is an acute, subacute or chronic infectious disease caused by the fungus *Histoplasma capsulatum*. Histoplasmosis, once thought to be invariably fatal, is now recognized as a relatively common benign (often clinically inapparent) or only moderately severe disease and less frequently as an overwhelming one. At least 30 per cent of the observed cases of histoplasmosis have occurred in children.

**Etiology.** *Histoplasma capsulatum* has two distinct growth phases. When cultivated on artificial media at room temperature, it produces a white, cottony, aerial, mycelial growth and a brownish-yellow subsurface growth. In tissues and when first cultivated on enriched media at 37° C., it grows in a yeast cell phase, having a relatively thick, translucent capsule. It can be identified in the mycelial culture by the characteristic tuberculate chlamydospores. The fungus has been isolated from dogs, mice, rats and horses, and from soil, principally adjacent to chicken houses and pigeon lofts, but also in damp places, along streams and in caves. There is no evidence that the disease is transmitted from man to man or from animal to man.

**Pathogenesis and Pathology.** The fungus apparently enters the body through the skin or through the mucous membrane of

FIG. 168. Histoplasmosis in infancy. A, An infant, aged 5½ months, with pyrexia, anemia, hepatosplenomegaly and leukopenia. Note site of sternal puncture; yeast cells of *H. capsulatum* were found in smears and cultures of the sternal marrow. B, Chest roentgenogram shows diffuse pneumonitis and a mediastinal mass. Diagnosis confirmed by autopsy. (Hild: *Am. J. Dis. Child.*, Vol. 63.)

the mouth, nasopharynx, respiratory tract or intestinal mucosa, producing an ulcerative lesion. The disease may manifest itself as a generalized process involving the reticuloendothelial system in the bone marrow, lung, liver, spleen and lymph nodes. The individual lesions are tubercle-like granulomas, occasionally with central necrosis; calcium is often deposited in the healing lesion.

**Clinical Manifestations. Severe form.** The progressive form of the disease, which is more likely to occur in infants and young children or in debilitated adults, is generally recognized only after it has reached a moderately advanced stage, when the clinical pattern may be suggestive of leukemia. The temperature is irregularly elevated from 101° to 103° F. The signs and symptoms vary considerably; there may be a mild gastrointestinal disturbance often with diarrhea, weight loss, malaise, irritability, pallor, indefinite joint and muscle pains or abdominal enlargement. Pneumonitis is common. In most cases there is enlargement of the spleen and liver. The roentgenogram of the chest may reveal scattered parenchymal lesions and/or enlarged mediastinal nodes, which on occasion are responsible for localized obstructive emphysema. Purpura, ecchymoses and melena may be present in the terminal stages. In children peripheral lymphadenopathy of a marked degree is uncommon. Meningitis with cerebrospinal fluid changes similar to

those of tuberculous meningitis has been observed.

**Mild and moderately severe forms.** In the decade of 1930 it became evident that a large number of persons living in the central and southern states bordering the Mississippi River and in the states of the Western Appalachian slope had what appeared to be calcified tuberculous lesions in the tracheobronchial lymph nodes and in the lungs, but with a negative reaction to tuberculin. Subsequently it was discovered that most of these persons had a positive skin reaction to histoplasmin. It now seems apparent that they were infected with *H. capsulatum* and in most instances were not aware of the time of the acute stage.

Thus it appears that histoplasmosis, like tuberculosis and coccidioidomycosis, may be a widespread infection, with common benign and rare severe forms, which sensitizes the human host to its antigen and whose lesions in the benign form heal by calcification, and which, like coccidioidomycosis, has a distinct geographic distribution. Noncalcified single and multiple focal lesions have been demonstrated in the lungs with associated involvement of the hilar lymph nodes which subsequently calcify. In neither stage are these lesions distinguishable from tuberculous lesions (Figs. 169, 170). When children with such lesions have positive skin reactions to histoplasmin and negative ones to tuberculin,

it is assumed that they have active (noncalcified) or healed (calcified) histoplasmosis. There is no evidence that persons who have such calcifications have any impairment of health or any increased likelihood to development of the severe, progressive form of the disease.

In a disease in which severe fatal forms and asymptomatic benign ones are recognized it would seem reasonable that there would be intermediate forms. *Histoplasma capsulatum* has been isolated from children with splenomegaly, ulcerations of the skin or mucous membranes and/or pulmonary infiltrations, who have recovered. These children have skin sensitivity to histoplasmin and complement-fixing antibodies.

**Laboratory Diagnosis.** Changes in the blood usually consist in a progressive hypochromic anemia and a leukopenia with a relative lymphocytosis. There may be a pancytopenia, suggestive of an aleukemic phase of leukemia; the platelets, however, are usually not reduced until late in the course of the disease. On occasion the parasites can be demonstrated in the white blood cells.

The yeast phase of the fungus as it occurs in the cells of the body appears as a small (1 to 5 microns), encapsulated oval body in the large mononuclear cells. The cellular elements of the bone marrow are otherwise normal. Thick-drop preparations or smears of the peripheral blood and bone marrow should be stained with Wright's or Giemsa's

FIG. 169. Examples of pulmonary and mediastinal calcifications in histoplasmin-positive and tuberculin-negative patients. A, Single pulmonary and mediastinal calcified masses strikingly similar to so-called healed pulmonary tuberculous complex. B, Multiple parenchymal calcifications suggestive of healed miliary tuberculosis.

FIG. 170. Roentgenogram of chest, showing fibrosis, calcification and cavity formation in the left upper lobe. Note similarity to chronic tuberculosis in apical area. The histoplasmin reaction was strongly positive; none to tuberculin. *Histoplasma capsulatum* was cultured from sputum. The patient regained his weight and was reported well one year after this roentgenogram was taken. (Johnson and Batson: Dis. of Chest, Vol. 14.)

stain. Biopsy material from lymph nodes or from the liver or spleen, as well as sputum or material swabbed from an ulcerative lesion, can also be smeared and stained by one of these methods.

**Technique of culture.** The technique to be followed varies somewhat with the material. Biopsy specimens are ground to a thin paste, using a minimal amount of sterile saline solution. Swabs from infected areas are placed in test tubes containing 1 to 2 ml. of sterile saline solution. Blood is mixed with heparin, rather than citrate, as an anticoagulant and is centrifuged at sufficiently high speed to allow separation of the white cells, which are pipetted off and placed in a test tube containing 1 to 2 ml. of sterile saline solution. After one hour, and again after twenty-four to forty-eight hours of incubation, the material is streaked heavily on duplicate screw cap bottles (25 by 50 mm.) containing slants of peptone or meat extract agar to which has been added plasma or blood serum to a concentration of 5 per cent and 50 units per milliliter of penicillin and 0.4 mg. per milliliter of streptomycin in the media. The use of bottles instead of Petri dishes or plates has decreased air contamination by fungi and permits small amounts of material to be studied. The bottles must be sealed; one bottle is incubated at 37° C., the other at room temperature. The cultures should be examined at intervals of three to four days and should not be considered negative until after an observation period of four weeks. Positive cultures which have been kept at 37° C. will frequently have colonies of yeast cells rather than of

mycelium. At room temperature *H. capsulatum* grows only in the mycelial phase, producing the characteristic tuberculate chlamydospores. The older the mycelial culture, the more likely are chlamydospores apt to be present. Thus in young cultures they may not be found, and the culture may be considered negative.

**Histoplasmin test.** The histoplasmin skin test resembles the tuberculin test. The testing material, a filtrate of a broth culture of *H. capsulatum*, is injected intracutaneously. The reaction is read at forty-eight hours; a positive reaction consists of an area of erythema with induration of at least 0.5 mm. in diameter. A positive reaction is evidence of sensitization to *H. capsulatum*, but does not indicate whether the infection is active. Conversion from a negative to a positive reaction within a few weeks or a positive reaction in infants is suggestive of an active infection. Persons with progressive disseminated histoplasmosis frequently fail to react to histoplasmin.

Serologic tests are useful to establish the presence of progressive infection.

**Differential Diagnosis.** Histoplasmosis may simulate a number of other clinical conditions. The presence of progressive anemia, leukopenia and hepatosplenomegaly requires differentiation from leukemia, the lipid storage diseases, Banti's syndrome, malaria and

brucellosis. Both extrathoracic and intrathoracic tuberculosis must be considered, and when there are persistent gastrointestinal signs, tuberculous peritonitis or enteritis must be included in the differential diagnosis. Ulceration of the skin or mucous membranes must be differentiated from actinomycosis, leishmaniasis and toxoplasmosis; irrespective of lymph node enlargement, Hodgkin's disease and other malignant lymphomas must be ruled out. Other systemic mycotic diseases and coccidioidomycosis in particular must be included in the differential diagnosis of the pulmonary infection.

**Treatment.** No chemotherapeutic or antibiotic agent has been found which satisfactorily inhibits the growth of *H. capsulatum* without injuring the tissue of the host. The usual antibiotics are completely without effect, and some of them may facilitate growth of the fungus. In the author's experience sulfonamides (triple sulfonamides) have seemed to offer the most benefit in doses sufficient to obtain blood levels of 15 to 20 mg. per 100 ml. Amphotericin B is being used, and there are some reports suggesting favorable effects. The drug is toxic, however, and should be used only on an experimental basis.

## COCCIDIOIDOMYCOSIS

(SAN JOAQUIN FEVER, VALLEY FEVER, DESERT RHEUMATISM, COCCIDIOIDAL GRANULOMA)

**Etiology.** Coccidioidomycosis is an infection caused by the fungus *Coccidioides immitis*. The minute spores of its so-called saprophytic phase are inhaled or, rarely, enter through an abrasion. They round up into spherules which develop endospores within doubly refractile walls, the characteristic sporangium of the so-called parasitic phase. These spherules do not spread from person to person or from animal to man; so the infection is not contagious. The mycelial form frequently occurs in pulmonary cavities, but no cases of contagion have been discovered. However, as they occur in nature and on surface cultures, the arthrospores (chlamydospores) of the "saprophytic phase" are highly infectious. Within the arid endemic areas of

California's San Joaquin Valley, in scattered regions in southern California, in central and southern Arizona and even in western and southern Texas, from three quarters to nine tenths of the population have been infected along with cattle, sheep, dogs and wild rodents. Infection is quickly acquired and apparently confers a permanent immunity. Therefore, where the population is stable, it is a childhood infection.

**Clinical Forms.** The human infection must be considered under two broad headings: (1) a benign, self-limited primary infection; and (2) a rare, disseminating, generally fatal disease.

**Primary coccidioidomycosis.** The incubation period varies from one to three weeks, with an average of ten to sixteen days. In 60 per cent of infected persons there are no clinical manifestations. Symptoms are influenzal in type, and the onset may be insidious, or abrupt with malaise, chills and fever. Night sweats and anorexia are common, and on occasion there is a persistent dry cough with which there may be a painful throat. There may be headache, backache, chest pain, which may vary from a mere sense of constriction to excruciating pleurisy with labored respirations, arthritis, phlyctenular conjunctivitis and skin rashes.

There may be a generalized, fine, macular erythema within the first day or two somewhat similar to the rash of measles or scarlet fever. The most frequent dermatologic manifestation, however, is erythema nodosum with or without erythema multiforme. These lesions develop in approximately 5 per cent of infected persons at the time sensitivity to coccidioidin is maximal, three to twenty-one days after onset of symptoms, although skin lesions may occur in persons otherwise asymptomatic.

Physical examination of the chest rarely discloses positive findings, even though roentgenography reveals extensive consolidation. Infrequently dullness, a friction rub or fine rales may be detected. Pleural effusions occur at times and may be so massive as to embarrass respiration. Like tuberculous pleural effusions, they may develop without preceding respiratory symptoms. Infrequently a cavity may develop in an area of pulmonary consolidation. There are usually no symptoms related to it, and the diagnosis is made from the roentgenogram. Occasionally, however, there is hemoptysis which, although it may recur and be alarming, is seldom so severe as to impair health. Dissemination of infectious

material from these cavities resulting in lesions in other areas is extremely rare. The infection appears to be focalized as well in persons with cavities as in those without them. Pulmonary residuals sometimes persist, but are not harmful. They pose problems of differentiation from tuberculosis.

**Disseminated or progressive coccidioidomycosis (coccidioidal granuloma).** Certain persons seem to lack ability to focalize the coccidioidal infection. Dissemination, which is rare and occurs mainly in males, especially in those of the dark-skinned races, usually follows the initial illness within six months, often without any interlude. The closest analogy is to progressive primary tuberculosis. Meningitis is the most serious of the disseminated lesions, clinically being similar to tuberculous meningitis. In white persons it is not unusual for meningitis to be the only extrapulmonary lesion. Papillomatous skin lesions and cold abscesses, both subcutaneous and osseous, occur most frequently in the dark-skinned races. The tendency to abscess formation is relatively more frequent in coccidioidal granulomas than in tuberculous lesions. Miliary dissemination and peritonitis are clinically and, except by demonstration of the etiologic agent, pathologically indistinguishable from tuberculosis. The case fatality rate of the disseminated infection is at least 50 per cent, and of meningitis practically 100 per cent.

**Diagnosis.** Diagnosis of the disseminated infection may be established by biopsy or at autopsy. If histologic examination demonstrates the characteristic double-contoured spherules with endospores and without budding, the diagnosis is certain. In both primary and disseminated infections recovery of the fungus by culture and animal inoculation is also diagnostic. Coverglass examination is not sufficient, since the diphasic character of the fungus should be demonstrated. Sputum is generally scanty in the primary infection, so that gastric lavage may be advisable, especially in children. The fungus will not withstand the concentration procedures used for tubercle bacilli. The material should be cultured or, after treatment with penicillin and streptomycin or 0.05 per cent copper sulfate, injected intratesticularly into a guinea pig. Any suspicious white fluffy fungus should be injected into a mouse or guinea pig to demonstrate diagnostic spherules. All cultures must be moist, and care must be exercised in handling them, since infections are frequently contracted in the laboratory.

**Coccidioidin test.** The test is specific except for occasional cross reactions in histoplasmosis and blastomycosis. Like the tuberculin test, a positive reaction does not distinguish between a recent or old infection unless preceded within a reasonably short time by a negative test. Obviously, its usefulness is restricted in residents of an endemic area. The coccidioidin is administered intradermally as 0.1 ml. of a 1:100 or 1:1000 dilution. The reaction generally reaches its peak at thirty-six hours and should be read at twenty-four and forty-eight hours. The criterion for a positive test is an area of induration more than 5 mm. in diameter. Patients with erythema nodosum suspected of being coccidioidal should have the weaker solution, since they are likely to be hypersensitive. Patients with disseminated infections are much less sensitive, a 1:10 dilution often being required to elicit a reaction. There is no danger of disseminating or activating a coccidioidal infection by a strong coccidioidin reaction, although there may be a systemic reaction as well as a local one. Coccidioidin does not evoke humoral antibodies, so that the skin test may precede serologic tests and provides information necessary for their interpretation.

**Blood and cerebrospinal fluid.** Serum precipitins and complement fixation appear after coccidioidin sensitivity has become demonstrable and persist during periods of anergy associated with overwhelming disseminated lesions. In general, the more severe the infection, the higher the titer of complement fixation. Humoral antibodies are generally not demonstrable in asymptomatic infections. The sedimentation rate is rapid in both primary and disseminated infections and is helpful in evaluating the clinical status. Eosinophilia is a common finding. The cerebrospinal fluid findings, other than a frequently encountered paretic type of colloidal gold curve, are similar to those of tuberculous meningitis.

**Roentgenography.** During the primary infection, roentgenograms of the chest may reveal no pulmonary changes, and those that occur are not diagnostic. Hilar adenopathy occurs frequently, and there may be single or multiple sharply circumscribed or soft feathery small pulmonary densities or larger consolidated areas. Pulmonary cavities, when present, tend to be thin-walled. There may be pleural effusions of variable extent. The osseous lesions of the disseminated infection are usually multiple with a predilection for

cancellous bone; the lesions often show considerable proliferation and are generally indistinguishable from those of tuberculosis.

**Treatment.** No drugs are known to be beneficial except for symptomatic relief. Salicylates, with or without iodides, may be given, especially when there is erythema nodosum. If a cavity develops and does not close after a month or two of bed rest, the patient may, unless the activity produces serious symptoms, be permitted up, provided he is kept from competitive sports and strenuous exertion. Most cavities disappear, even those which have existed for a year or so. If they increase in size, are repeatedly secondarily infected, or produce severe hemoptysis, surgical removal is recommended.

During the acute infection, in order to reduce the danger of dissemination, rest is advisable until the child is symptom-free and the sedimentation rate approaches normal. When dissemination occurs, little can be done to influence the course. Vaccines have been advocated, but their value has not been

established. Occasionally excisions, amputations and fusion operations have been beneficial in the treatment of osseous lesions. Treatment, in general, consists in the supportive measures used for tuberculosis.

# PARASITIC DISEASES

## HELMINTHIC AND ARTHROPOD DISEASES

Helminths and arthropods are Metazoa, i.e., many-celled animals, and both belong to the invertebrates. The helminths, or parasitic worms, comprise three large groups, the Nematoda (roundworms), the Platyhelminthes (flatworms) and the Hirudinea (leeches). The arthropods constitute the largest group in the animal kingdom and include centipedes, scorpions, spiders, ticks, mites and insects.

Table 79. Epidemiology of the More Important Helminthic Infections Encountered in Pediatric Practice

<i>Peroral Exposure</i>	<i>Transmission Source</i>	<i>Helminth and Stage Involved</i>	<i>Disease</i>
1. From raw or inadequately processed foods	a. Fruits and vegetables	Ascaris and Trichocephalus (fully embryonated eggs)	Ascariasis, trichocephaliasis
	Water cress	Fasciola (encysted metacercariae)	fascioliasis
	Water nuts	Fasciolopsis (encysted metacercariae)	Fasciolopsiasis
	b. Meat		
	Pork	Trichinella (encapsulated larvae)	Trichinosis
		Taenia solium (encapsulated cysticerci)	Teniasis
	Beef	Taenia saginata (encapsulated cysticerci)	Teniasis
	Bear meat	Trichinella (encapsulated larvae)	Trichinosis
	c. Fish	Diphyllobothrium latum (sparganum larvae)	Diphyllobothriasis
		Clonorchis, Opisthorchis, Metagonimus, Heterophyes (encapsulated metacercariae)	Clonorchiasis, etc.
	d. Crabs and crayfish	Paragonimus (encapsulated metacercariae)	Paragonimiasis
2. From fresh water	Cyclops and Diaptomus	Dracunculus (infective larvae); Sparganum (procercoid larvae)	Dracontiasis, sparganosis
3. From person-to-person contact	Anus→fingers→mouth or anus→clothing→fingers→mouth	Enterobius and Hymenolepis nana (fully embryonated eggs)	Oxyuriasis, hymenolepiasis
4. From contaminated soil	Dirty toys or candy; eating earth	Ascaris and Trichocephalus (fully embryonated eggs)	Ascariasis, trichocephaliasis
5. From contact with domestic mammals	a. Dog feces	Echinococcus (eggs)	Hydatid disease
		Toxocara canis (fully embryonated eggs)	Visceral larva migrans
	b. Cat feces	Toxocara cati (fully embryonated eggs)	Intestinal toxocariasis
	c. Dog and cat fleas	Dipylidium caninum (infective-stage larvae in fleas)	Dipylidiasis
	d. Rodent fleas	Hymenolepis diminuta (infective-stage larvae in fleas)	Hymenolepiasis
<i>Percutaneous Exposure</i>	<i>Transmission Source</i>	<i>Helminth and Stage Involved</i>	<i>Disease</i>
1. From infested ground		Hookworms and Strongyloides (filariform larvae)	Hookworm disease, strongyloidiasis
2. From infested fresh water	Mollusca-intermediate hosts in water	Schistosoma species (cercarial larvae)	Schistosomiasis; schistosome dermatitis
3. From blood-sucking insects	Mosquitoes, coffee flies, mango flies, etc.	Filaria worms (filariform larvae)	Filariasis

Owing to the greater opportunities for exposure, diseases produced by most animal parasites occur more frequently in children than in any other age group. Furthermore, children are more likely to manifest acute evidences of these diseases, because in the early years of life there is no immunity or tolerance to many of the parasites. Later, as humoral and cellular resistance develops, the

body tends to become more accustomed to the invader and may even develop a relatively solid immunity. Thus the morbidity and the mortality of animal parasite diseases are higher in childhood than in later life, and as a general rule evoke more conspicuous and severe symptoms in the first decade of life.

For information on the comparative epidemiology of these diseases see Table 79.

### *Infections Produced by Roundworms (Nematoda)*

All the important roundworm infections are produced by species belonging to the phylum Nematoda, which includes the true roundworms. These are elongated, cylindroid, unsegmented animals covered with a tough, relatively impermeable cuticle secreted by the underlying tissue layer, the hypodermis. They have a complete digestive tract, consisting of a mouth which is frequently provided with lips, teeth or other organs designed for penetration and attachment, a muscular esophagus, a midgut in which digestion of food takes place, and a hindgut, or rectum. The nervous system is primitive and is elaborated only at the oral end. A conspicuous body cavity contains the organs of excretion and reproduction. The sexes are usually separate. The female reproductive opening (vulva) is mid-ventral in position, near the equatorial plane or anterior to this level. The male reproductive system joins the rectum to form a cloaca, which opens externally at or near the posterior end of the body.

The most important roundworm infections (nematodiasis) are ascariasis, oxyuriasis, trichocephaliasis, the hookworm infections, strongyloidiasis, trichinosis, the filariases and dracontiasis.

#### **ASCARIASIS**

**Etiology.** Ascariasis is produced by the giant roundworm, *Ascaris lumbricoides*, which normally lives in the lumen of the small intestine. The mature female worm is about the size of a pencil, and the male is about one fifth smaller. Both sexes have three fleshy lips surrounding the triangular mouth, and both taper to a sharp posterior end, although the male is curved ventrally at the posterior extremity. The female lays approximately 200,000 eggs each day. These are infertile if males are lacking, and some are infertile if the female is just beginning to

oviposit. The fertile eggs are passed in the patient's feces in the one-celled stage. They are broadly ovoidal, measure 35 to 50 microns in cross section by 45 to 75 microns in greatest diameter, are provided with a thin, resistant inner shell, a thick hyaline middle shell and a mammillated outer covering which is usually bile-stained. Within the shell covering is a densely granular spherical egg cell (Fig. 171).

**Epidemiology.** Ascariasis is widely distributed through the warm climates of the world and extends into the temperate zones as far north and south as latitude 40 degrees. The fertile eggs are able to survive practically all external conditions except heat. When the egg is deposited on the ground, in cracks between stones or on the floor of the house, it proceeds to embryonate and in warm weather within nine days or more contains a motile first-stage larva. A week later, during which the larva moults once, the egg is infective. It does not hatch on the soil, but only after being swallowed. In favorable environments, as in the Gulf Coast area of the United States, the embryonated eggs may remain viable during the infective stage for several months or even years (Headlee, 1936). The worms are harbored principally by young children, who are more frequently exposed to infection and are the primary source of supply for "seeding" the soil with eggs. This is due to promiscuous defecation by small children who find it more convenient to deposit their excreta where they are playing than to use toilets. The eggs develop in the top soil, and children take some of them into the mouth on contaminated fingers, candy or play objects, or as a result of eating dirt. Where these unsanitary conditions prevail 60 to 100 per cent of children from one to ten years of age are infected with *Ascaris*. Older children and adults are parasitized to a less degree and can usually trace their in-

FIG. 171. A, Fertilized egg of *Ascaris lumbricoides*.  $\times 550$ . B, Unfertilized egg of *Ascaris lumbricoides*.  $\times 550$ . C, Egg of *Diphylllobothrium latum*.  $\times 550$ . Nauck: *Lehrbuch der Tropenkrankheiten*. Courtesy of Georg Thieme Verlag, Stuttgart.)

fections to sources provided by the younger groups.

Ascariasis is encountered occasionally among children in the northern United States, but the southern Appalachians and their extension into the Ozarks and the Gulf Coast states constitute the regions of high endemicity in the United States. Hard clay soils are most favorable for the development of *Ascaris* eggs, in contrast to moist sandy humus for those of hookworms.

Hogs are infected with an *Ascaris* morphologically indistinguishable from that in man, but hog *Ascaris* is rarely if ever in-

fective for human beings under natural conditions.

**Pathology.** When infective-stage *Ascaris* eggs are swallowed and reach the duodenum, they hatch, and the escaping larvae enter the intestinal wall. The larvae penetrate into the mesenteric lymphatics or venules, commonly migrating through the liver, and are carried to the lungs through the right side of the heart. From the pulmonary capillaries the larvae invade the air sacs, causing the discharge of a minute pool of blood at each site of escape. An acute cellular infiltration typically occurs in the immediate vicinity,

temporarily blocking the passage of the larvae up the respiratory tree (Fig. 172). If the number of larvae migrating through the lungs is appreciable, an atypical pneumonia results.

After a second larval moult in the lungs the third-stage larvae reach the epiglottis, are swallowed and become established in the small intestine. Between the sixtieth and seventy-fifth days after the eggs have been swallowed, mature worms mate, and the females begin their egg-laying. If the worms become irritated by their environment, as, for example, owing to digestive disturbances or fever, they may pass down the bowel and be spontaneously evacuated; or they may enter the stomach to be vomited or escape through the nares. They may block the appendiceal lumen, perforate the intestinal wall, block the common bile duct, migrate into the parenchyma of the liver or reach the pleural cavity. Extensive destruction of the hepatic parenchyma may occur as a result of their movements, their toxic metabolites and those of their eggs.

**Clinical Manifestations.** During their temporary stay in the lungs the young worms may cause an atypical pneumonia. The sensitization produced by these migrating larvae is responsible for the manifestations of *Ascaris* allergy frequently observed, including asthma, urticaria and eosinophilia.

Intestinal infection with *Ascaris* may be apparently symptomless, or there may be such manifestations as nausea and vomiting,

anorexia, loss of weight, insomnia, slight rise in temperature, nervousness and irritability, or physical and mental languor. The most common complaint of infected children is intestinal colic. Some patients are highly intoxicated by the by-products of the worms and may have a rapid rise in temperature. Acute symptoms accompany ectopic excursions of the worms. A mass of writhing worms knotted together frequently produces acute intestinal obstruction, at times resulting in perforation of the wall, in intussusception or in paralytic ileus.

**Diagnosis.** The diagnosis is commonly made by the recovery of fertile or infertile eggs in microscopic fecal films (Fig. 172). Direct unconcentrated films usually provide this evidence after the mature females have begun to oviposit. If only male worms occur (in less than 5 per cent of infections), clinical diagnosis may be confirmed by the therapeutic test. From time to time adult or immature worms passed in the stool or vomited or discharged from the nostril require diagnosis. Occasionally, during barium studies of the gastrointestinal tract for other purposes, *Ascaris* are demonstrated.

**Prognosis.** Except when large numbers of *Ascaris* larvae in the lungs initiate lobular pneumonia or when adult worms produce intestinal obstruction or perforation, the prognosis is good to excellent, provided a specific anthelmintic is administered.

**Prevention.** In highly endemic areas re-

FIG. 172. Larva of *Ascaris lumbricoides* in migration through the lung, in center of small pool of blood, with leukocytic infiltration.  $\times$  ca. 200. (After Mackie, Hunter and Worth: A Manual of Tropical Medicine.)

exposure is the rule, and reinfection takes place about every three months. Thus both the physician and the public health officer are concerned with problems of control. Children as well as adults must have comfortable, clean toilets and must be taught to use them habitually. If soil in a courtyard is heavily seeded with *Ascaris* eggs, the top 2 inches of soil should be turned under. Finally, all infected persons should receive specific medication.

**Treatment.** The older drugs used for removal of *Ascaris* from the intestine are either not sufficiently effective (e.g., thymol) or are dangerous in full therapeutic doses (e.g., oil of chenopodium). Until recently the drug of choice was hexyresorcinol crystoids, a safe, highly efficient ascaricide. The patient is prepared the night before treatment with saline purgation, preferably with Glauber's salt (sodium sulfate),  $\frac{1}{2}$  ounce or 15 gm. (adult dose) in a glass of water, or a fractional amount for small children. On the morning of treatment, Crystoids Anthelmintic (in 0.1- or 0.2-gm. hard gelatin pills) are administered on an empty stomach. The pills must be swallowed without being opened, to prevent a superficial, temporary, painless erosion of the buccal mucosa. For small children the pills may be placed in the back of the mouth with a finger or in a teaspoonful of jelly and washed down with a half-glass of water. The dose is 0.1 gm. per year of developmental age up to 1 gm., in a single dose per day. Food is prohibited for four to five hours. A post-treatment saline purge is recommended to evacuate dead and dying worms and prevent further systemic intoxication. Though this drug is about 90 per cent effective in removing *Ascaris* from the intestine, it does not kill migrating larvae.

In ascariasis complicated with hookworm infection, Crystoids Anthelmintic may be safely administered and are about 75 to 85 per cent efficient against hookworms. Hookworm infection should not be treated with tetrachloroethylene if *Ascaris* is present, without an accompanying ascaricide. This combination of infections may be treated with tetrachloroethylene and oil of chenopodium in the proportion of 9 to 1 in gelatin capsules or on a teaspoon with sugar. The patient is prepared with saline purgation the night before and given 0.2 cc. of the mixture for each year of developmental age up to fifteen years, after which the full dose of 3 cc. is prescribed. Post-treatment purgation is advised, and no food is allowed until after a

copious defecation. *Piperazine citrate* (diethylene diamine) is an almost ideal drug for this infection. In a pleasant-tasting, fruit-flavored syrup (Antepar) the preparation contains the citrate equivalent of 100 mg. of piperazine hexahydrate per milliliter. This drug requires no pretreatment or post-treatment purgation and no fasting, and in recommended doses produces no side effects. A highly satisfactory dosage schedule is as follows: for children weighing 15 to 30 pounds, 2.5 ml. twice daily; 30 to 60 pounds, 5 ml. twice daily; and over 60 pounds, 10 ml. twice daily; for four to seven days.

## TOXOCARIASIS AND VISCERAL LARVA MIGRANS

See also Löffler's Syndrome, page 801, and Tropical Eosinophilia, page 602.

**Etiology.** Intestinal toxocariasis is produced by *Toxocara cati*, the cat ascarid, and *Toxocara canis*, the dog ascarid. There are possibly eighteen authentic records of intestinal infection with *T. cati* in children and only one questionable record of *T. canis*. By contrast, extraintestinal infection (visceral larva migrans) seems to be characteristic of *T. canis*. The life cycle of these worms in their normal hosts parallels that of human *Ascaris*, including a required migration through the lungs.

**Epidemiology.** Eggs of *Toxocara* embryonate on the ground. When they get into the mouths of children and reach the duodenum, they hatch, and the escaping larvae penetrate into the intestinal wall. Cumulative reports indicate that extraintestinal infection with the larval stage of *T. canis* (visceral larva migrans) is relatively common in children in the United States, especially in the deep South.

**Pathology.** Clinical investigations supplemented by experimental studies have shown that *T. canis* undertakes a migration through the viscera, but fails to develop. Usually it becomes trapped in a granulomatous tissue reaction, most frequently in the liver, at times in the lungs and eyeballs (Fig. 173), and rarely in the brain and other soft tissues. If thousands of infective-stage eggs are ingested, there may be a large number of granulomas, one surrounding each larva which has hatched and has attempted pulmonary migration. Once trapped, the larva may soon die and become fibrosed or calcified, or it may survive for months, but it does not proceed with normal growth in the

FIG. 173. Visceral larva migrans. Second-stage larva of dog ascarid, *T. canis*, in center of granuloma in vitreous chamber of human eye.  $\times 220$ . (After Wilder; courtesy of Armed Forces Inst. of Path., and Tr. Am. Acad. Ophth. & Otolaryng.)

human body and probably never completes its migration back to the intestinal tract to develop into an adult worm.

**Clinical Manifestations.** The evidence may be solely a persistent eosinophilia, or there may be hepatomegaly, multiple pulmonary infiltrations, fever, cough, hyperglobulinemia or symptoms referable to the brain or eye.

**Diagnosis.** Diagnosis is made by demonstration of the larvae in granulomatous areas of the liver (biopsy), from enucleated eyes or at autopsy.

**Prognosis.** In limited invasions visceral larva migrans is a relatively benign disease, except when the larvae are trapped while migrating ectopically through the brain or eyeball; in extensive infections the prognosis is grave.

**Prevention.** Periodic deworming of household dogs is indicated.

**Treatment.** No specific therapy is known.

## OXYURIASIS

(ENTEROBIASIS)

**Etiology.** Oxyuriasis is produced by the pinworm *Enterobius vermicularis* (seatworm, Oxyuris of older textbooks). The adult worms are small (males, 2 to 5 mm. in length, and curved ventrally at the posterior end; females,

8 to 13 mm. in length, robust in the middle and drawn out into a long sharp point posteriorly). The worms live attached by their lips to the mucous coat of the cecum and appendix. Gravid worms become detached, migrate down the bowel and characteristically crawl out the anus onto the perianal and perineal skin, where each female deposits several thousand eggs in a sinuous track. Eggs are laid within the bowel in only about 5 per cent of infections, and these are usually infertile or immature. The eggs laid outside the anus are elongated, ovoidal, flattened on one side, with a thick, slightly opalescent shell, and measure 50 to 60 by 20 to 30 microns. They contain a coiled larva at the time of oviposition (Fig. 174). At most they require only a few hours after deposition to become infective.

**Epidemiology.** This infection is cosmopolitan in distribution. Children are particularly susceptible, and those in large families and dormitory groups are more heavily parasitized than the population at large. They are exposed to infection by scratching the itching skin around the anus, where the eggs are lodged, or from soiled night garments or undergarments, bed linen or contaminated objects in the room, and in this way getting the eggs onto the tips of their fingers and then into their mouths; from breathing air-

FIG. 174. Fully embryonated egg of *Enterobius vermicularis* obtained by perianal swabbing.  $\times 800$ . (From Cram: Introduction to Nematology. Bureau of Plant Industry, Washington, D.C.)

borne eggs; and occasionally as a result of reinfection, in which eggs hatch on the perianal skin and the larvae migrate inside the anus and up to the cecal area, where they mature. Fertile eggs remain infective in the average environment for at least nine days.

**Pathology.** When viable eggs are swallowed and pass down the digestive tract, they hatch at the duodenal level, and the escaping larvae migrate directly to the cecum, become attached and develop into adults in about forty-five days or less. They usually produce no appreciable damage at the site of attachment, although they may cause hemorrhage from the appendiceal wall or provide an opening for pathogenic bacteria which may provoke a submucous abscess. Gravid worms, crawling out the anus, usually at night, frequently cause a severe pruritus, and the inevitable scratching results in scarification and secondary infection of the skin. In the female patient the gravid worms may enter the genital tract, cause a salpingitis, become encapsulated in the tubules or enter the peritoneal cavity and provoke encapsulation.

**Clinical Manifestations.** The appendiceal lesions occasionally produce symptoms of acute or subacute appendicitis, with indications for excision of the organ. Pruritus ani is frequently complicated by bacterial invasion of the skin and the production of weeping, eczematous areas. Children, especially young girls, may have irritability, loss of appetite and weight, and insomnia, resulting in chronic emotional disturbances. Vaginitis has been ascribed to direct invasion by the worms. Eosinophilia may be produced, but is not present in all cases.

**Diagnosis.** Oxyuriasis is rarely diagnosed by fecal examination. The eggs (Fig. 174) can usually be recovered in one to several swabbings of the perianal and perineal skin, preferably in the morning before dressing, bathing or defecation.

A simple and probably the most efficient anal swabbing technique consists in the use of a 2-inch length of adhesive-cellulose tape, placed sticky side out on the end of a 3-by-1-inch clean microscope slide held in place with the thumb and index finger. As the tape is brought in contact with the anal sphincter and the perianal folds, it collects *Enterobius* eggs among the flecks of mucus and cellular debris. After swabbing, the tape is placed flat, sticky side down, on the slide. It may be examined microscopically at any convenient time by allowing a drop or two of toluene to filter between the slide and the tape.

**Prognosis.** This is usually good. When the adult worms all spontaneously migrate out of the bowel or are removed by enema or catharsis, the infection may be permanently eliminated, unless auto- or heteroreinfection occurs.

**Prevention.** Scrupulous personal and group hygiene is advised, but in itself will not eradicate oxyuriasis. Accurate diagnosis and treatment of all infected persons in a household, repeated several times if necessary, constitute an integral part of the control program.

**Treatment.** Gentian violet medicinal is specific for the treatment of oxyuriasis. The 0.012-gm. and 0.03-gm. four-hour enteric-coated Seal-Ins or Enseal tablets are recommended, in order to permit the drug to be carried to the lower ileum or cecum before it is released. No pretreatment or post-treatment purgation is needed. The tablets are administered orally, three times a day for seven to ten days, discontinued for one week and then repeated. The individual dose is one small tablet (0.012 gm.) for children four to six years; two small tablets for those six to eight years; and one large tablet (0.03 gm.) for those eight to twelve years. The first period of treatment usually kills all the mature and maturing worms. The second period of treatment after a week's intermission is designed to take care of larvae hatched from eggs which might have been swallowed during the period of treatment. The drug is best tolerated when given with meals. Gastrointestinal irritation sometimes results from a defect in the enteric coating of the tablets. If they crack when placed under running

water, they should be discarded. Oxytetracycline (Terramycin) has as high a cure rate as gentian violet, provided all infected persons in a group are treated simultaneously and complete the full course of treatment. Brown (1952) used the following dosage schedules: age two to five years, 100 mg. four times daily for two days, then 50 mg. four times daily for two days, then 50 mg. daily for fourteen days; age six to ten years, 250 mg. four times daily for two days, then 250 mg. twice daily for two days, then 250 mg. daily for fourteen days; age eleven years and up, 500 mg. four times daily for two days, then 250 mg. twice daily for two days, then 250 mg. daily for fourteen days. Probably the most effective and harmless drug for oxyuriasis is *piperazine citrate* in a pleasant-tasting, fruit-flavored syrup (Antepar). It is prescribed in the following daily schedule: up to 15 pounds weight,  $\frac{1}{2}$  teaspoonful; 16 to 30 pounds, one teaspoonful; 31 to 60 pounds, 2 teaspoonfuls; and over 60 pounds, 4 teaspoonfuls of the syrup (each teaspoonful contains the equivalent of 500 mg. of piperazine hexahydrate). Completely successful results have been reported with a regimen of seven days' treatment, seven days' rest, seven days' treatment, seven days' rest and a final seven days' treatment. This preparation is easy to administer and, in the prescribed doses, produces no side effects.

All infected persons in a family or dormitory *must* be treated simultaneously. Even if *Enterobius* is completely eradicated from a household, periodic reinfection may be anticipated from outside contacts.

## TRICHOCEPHALIASIS

### (TRICHURIASIS)

**Etiology.** This infection is produced by the whipworm, *Trichocephalus trichiurus* (*Trichuris trichiura*), whose body is composed of two portions, a capillary anterior three fifths and a fleshy posterior two fifths. The males measure 30 to 45 mm. in length and are coiled at the posterior end. The females measure 35 to 50 mm. in length and have a club-shaped posterior end. These worms live with their anterior ends attached to the mucous coat of the cecum and appendix and, in heavy infections, in the adjacent parts of the ileum and ascending colon, and even in the sigmoid colon and rectum. The females daily lay a few thousand barrel-shaped eggs, which have mucus-like polar

plugs and are commonly bile-stained (Fig. 175).

**Epidemiology.** Whipworm infection is widely distributed in warm, moist climates. It is most common in children over five years of age, but may be prevalent in younger patients. The eggs passed in feces and deposited on moist, shaded soil require ten to fourteen days to develop to the infective stage, at which time each contains a coiled larva. When ripe eggs get into the mouth and are swallowed, they hatch at the level of the duodenum, and the escaping larvae slowly migrate to the cecum or appendix, become attached, and in about three months develop into adult worms.

**Pathology.** At each site of attachment there is a microscopic focus of inflammation. Toxic by-products at times provoke allergic manifestations, but usually the infection is well tolerated unless the worm burden is heavy (i.e., several hundred), as it frequently is in the tropics or the moist subtropics. In heavy infections the worms colonize the intestinal mucosa from the posterior level of the ileum almost to the anal sphincter.

**Clinical Manifestations.** Many persons, especially in the southern United States, harbor a few worms without apparent symptoms, but a small proportion experience loss of appetite, loss of weight, insomnia, physical and mental apathy or nervous symptoms. Heavily infected patients typically have a secondary anemia, with pallor, shrunken skin, dull eyes, dry hair and, at times, edema of the abdomen and lower extremities. In addition to the erythropenia there may be a neutropenia with monocytosis and a moderate eosinophilia. Children may fail to de-

FIG. 175. Egg of *Trichocephalus trichiurus*, as seen in freshly passed feces.  $\times 666$ . (After Faust, in Brennemann's Practice of Pediatrics. Courtesy of W. F. Prior Co.)

FIG. 176. Prolapse of rectum in a Louisiana child, due to heavy infection with *Trichocephalus trichiurus*, showing many worms attached to the rectal mucosa. Symptoms were relieved after hexylresorcinol enemas. (Photo, courtesy of Dr. J. C. Swartzwelder.)

velop physically or sexually. In heavy infections there is profound irritation of the bowel wall, resulting in a bloody, mucous diarrhea, at times with an associated prolapse of the rectum (Fig. 176).

**Diagnosis.** Diagnosis is made on the recovery of the characteristic eggs (Fig. 175) in direct or concentrated fecal films.

**Prognosis.** Prognosis is good in most patients, especially if a majority of the worms are removed by the use of anthelmintics.

**Prevention.** This consists in the habitual use of comfortable sanitary toilet facilities and the sanitary disposal of sewage. Children must be encouraged not to take contaminated objects and dirt into their mouths.

**Treatment.** In Latin America the fresh sap of the bastard fig tree (*Ficus glabrata*), referred to as *leche de higuérón*, is specific in its action on these worms. It is administered periodically in the amount of 2 ounces (60 cc.) to children or adults and is well tolerated. No purgation is required before or after its administration. This drug, either in its crude or refined state (ficin), is not available in the United States.

Tetrachloroethylene with oil of chenopodium, in the proportion of 9 to 1, is moderately efficient and safe. Purgation with Glauber's salt (sodium sulfate) (adult dose,  $\frac{1}{2}$  ounce or 15 gm.) on the night before treatment is followed in the morning with a high retention enema of physiologic saline

solution to wash out viscous feces adherent to the worms. Then the anthelmintic mixture is administered orally on an empty stomach in the amount of 0.2 cc. per year of apparent age up to fifteen years, when the adult dosage of 3 cc. is prescribed. Two hours later purgation with Glauber's salt is repeated. No food is allowed until copious stools have been passed. Treatments at weekly intervals may be necessary in order to reduce the infection below clinical level.

When whipworms are attached to the wall of the lower colon and rectum, a high retention enema of the following emulsion is recommended: 1 gm. of hexylresorcinol Crystoids for each 300 cc. of a 10 per cent mucilage of acacia, to which 30 gm. of fine kaolin are added to reduce colonic cramps. Several successive enemas may be required to remove all the worms. This enema should be preceded by a cleansing one, preferably a tepid physiologic saline solution.

The clinical introduction of the cyanine dye *dithiazanine* for treatment of intestinal roundworm infections has provided for the first time an eminently satisfactory drug against *Trichocephalus* infection. When administered in coated tablets by mouth (adult dose: 200 mg., three times a day) for five or more days, depending on the severity of the infection, this anthelmintic is highly effective for removal of these worms without producing side effects. Since it is also valuable

for treatment of ascariasis, it is particularly suitable for use in combined *Trichocephalus* and *Ascaris* infections.

## HOOKWORM INFECTION

**Etiology.** These diseases are produced by certain species of hookworms which parasitize man: *Necator americanus*, the so-called American hookworm; *Ancylostoma duodenale*, the so-called Old World hookworm; and *Ancylostoma braziliense*. The first two are exclusively parasites of man; *A. braziliense* is normally a parasite of dogs and cats. These worms are 7.5 to 13 mm. long and 0.3 to 0.4 mm. in greatest breadth. The males are slightly smaller than the females. The mouth of *Necator* is provided with a pair of upper and a pair of lower cutting plates; that of *Ancylostoma*, with two or three pairs of upper teeth. The females have a bluntly pointed caudal extremity and a vulvar opening midventral in position near the equatorial plane. The caudal extremity of the male is drawn out into an umbrella-like expansion, the copulatory bursa. These worms are attached by their mouth capsule to the mucosa of the small bowel, typically at the level of the duodenum, jejunum and adjacent portion of the ileum.

After insemination each female hookworm lays several thousand eggs a day. These eggs (Fig. 177) are broadly ovoidal, thin-shelled and hyaline and measure 60 to 76 by 36 to 40 microns. They are usually in an early stage of development when evacuated, but in constipated stools may be more advanced in their development (Fig. 177, right).

**Epidemiology.** *Necator americanus* is the tropical hookworm of the Eastern Hemi-

sphere; it is the only widely distributed hookworm in the Americas, including the southern United States. *Ancylostoma duodenale* is the hookworm of the Mediterranean basin and similar latitudes in Asia and is the more common species on the Pacific coast of South America. *Ancylostoma braziliense* has a spotted distribution in warm climates. Intestinal infection with this species appears to be limited almost exclusively to canine and feline hosts.

When eggs of *Necator* and *A. duodenale* are evacuated from the human bowel and deposited on a moist, sandy humus soil in a shaded site in warm climates, they embryonate rapidly and hatch in twenty-four to forty-eight hours. The escaping larvae feed ravenously on bacteria and organic debris, grow, moult, feed again and, between the fifth and tenth days, transform into infective-stage larvae. Human exposure occurs when these third-stage larvae come in contact with the skin, as when persons walk barefooted on or handle infected soil. Infants and small children are seldom exposed to infection except in hyperendemic areas. Older children and young adults, especially males, are most frequently parasitized and in highly endemic areas are subject to repeated infection. Thus man initiates the extrinsic phase of the life cycle by discharging hookworm eggs on the soil and, in turn, picks up the infection by direct contact with the soil.

The human, canine and feline strains of *A. braziliense* are physiologically distinct. Man acquires intestinal infection from the human strain, and cutaneous larva migrans (creeping eruption) from canine or feline strains.

FIG. 177. Eggs of human hookworm, *Necator americanus*, as seen in freshly passed feces. Left, 4-cell stage; right, maturing embryo.  $\times 666$ . (After Faust, in Brennemann's Practice of Pediatrics. Courtesy of W. F. Prior Co.)

FIG. 178. Cutaneous larva migrans of the left foot, showing the serpiginous tunnel produced in the deeper layers of the skin by infective-stage larva of a hookworm (probably *Ancylostoma braziliense* of the dog or cat). On the left, the older part of the tunnel, with evidence of pyogenic inflammation; on the right, the inner part of the tunnel, with the larva in the most advanced position. (Courtesy of Dr. Alex J. Steigman and P. Hess.)

**Pathology.** The infective-stage larvae of the human strains invade the human skin through hair follicles or under particles of desquamating epidermis. They migrate to the cutaneous blood vessels, enter the venules, are carried to the lungs through the right side of the heart and lodge in the pulmonary capillaries, where a third larval moult occurs. From the capillaries they penetrate the alveoli, migrate up the respiratory tract, pass over the epiglottis and are swallowed. On arrival in the small bowel they develop a temporary mouth capsule, become attached to a villus and begin to digest the tissues and suck blood. They then develop a permanent mouth capsule under the earlier one, which is now shed, become sexually mature and copulate. In five to ten weeks after invasion of the skin the females begin to lay eggs.

Temporary trauma and tissue reaction develop at the sites where the larvae invade the skin and again after escape of the larvae from the pulmonary capillaries into the air sacs, but these are not serious unless the cutaneous lesions become secondarily infected or the number of invading larvae is large. After attachment to the villi in the small bowel, the adolescent worms secrete lytic juices which digest the epithelium and the walls of the villous blood capillaries. This partially predigested food of blood and epithelial cells is now sucked into the intes-

tine of the worm, in part used as nourishment, but to a greater extent passed through the worm's body as a source of oxygen, since hookworms are primarily aerobic in their metabolism. Once this blood pumping is well under way, each worm may deprive the victim's body of as much as 0.67 ml. each day. The blood loss can be readily compensated if the number of worms is small, but frequently, when the number is more than fifty or the nutritional balance of the host is already precarious, decompensation occurs, with a resultant microcytic hypochromic anemia. This is the essential factor in hookworm disease.

**Clinical Manifestations.** As the intestinal infection develops, either rapidly as a result of a heavy single inoculation or cumulatively as a result of repeated exposure, digestion becomes disturbed and the stools are usually unformed, contain undigested food, and frequently are tarry with decomposed blood. Absorption of by-products of the worms results in systemic toxemia, but the more profound manifestations are the result of continued loss of blood. The skin becomes harsh and has an ashen pallor, or may have an icteric tinge. The eyes are dull, and the hair is lusterless. Owing to the anemia, there is a decreased oxygen-carrying capacity. The heart works at increased speed in an attempt to oxygenate the tissues and becomes more or less permanently dilated. Mental apathy is pronounced. These conditions are more marked in children than in adults, and physical growth and sexual development are delayed.

In creeping eruption, *cutaneous larva migrans*, resulting from infection with canine or feline strains of *A. braziliense*, less commonly the cosmopolitan dog hookworm *A. caninum* and rarely the human hookworms *N. americanus* and *A. duodenale*, the larvae penetrate to the deeper layers of the skin, but, being unable to enter the peripheral blood vessels, continue to migrate for months (*larva migrans*) through serpiginous tunnels in the skin. This produces an inflamed appearance of the somewhat elevated channels, which usually become infected as a result of scratching the pruritic lesions (Fig. 178).

At the end of the incubation period of human intestinal hookworm infection there is usually a moderate neutrophilic and eosinophilic leukocytosis. Later there is a neutropenia with monocytosis; there is also hypoproteinemia. In chronic infections the

hypochromic anemia may be replaced by a hyperchromic macrocytic anemia. There is frequently a pre-existing state of malnutrition with a conspicuous hypoproteinemia, which is accentuated by the hookworm disease.

**Diagnosis.** Diagnosis is based on identification of eggs (Fig. 177) in the stool.

**Prognosis.** Prognosis is usually good with specific treatment, provided reinfection is controlled, the hemoglobin content is returned to normal and an adequate, balanced diet is provided.

**Prevention.** This consists in (1) detection and thorough treatment of all infected persons to reduce soil contamination; (2) provision for, and use of, sanitary toilets; and (3) the habitual use of shoes in hookworm areas. Children on vacation in areas where hookworm infection exists should be warned about the danger of going barefooted.

**Treatment.** Several efficient anthelmintics are available, although not all are eminently safe. Before specific medication is undertaken it is desirable to provide the patient a well balanced, nutritious diet, reinforced with iron (ferrous sulfate). One or more blood transfusions may be desirable. After a week or ten days specific treatment may be safely undertaken. Liver therapy is indicated only if there is a macrocytic type of anemia.

Thymol, oil of chenopodium in full therapeutic doses and carbon tetrachloride are too toxic for general use. *Tetrachloroethylene* is well tolerated and has an efficiency of 90 per cent or more for worm removal, provided it is fresh and is kept in a cool place. It is preceded the night before by purgation with Glauber's salt (sodium sulfate) (adult dose,  $\frac{1}{2}$  ounce or 15 gm. in a half-glass of water). The following morning, on an empty stomach, the drug is given in gelatin capsules or on a spoon with sugar, in the amount of 0.2 cc. for each year of developmental age up to fifteen years, after which the adult dosage of 3 cc. is prescribed. Two hours later purgation with Glauber's salt may be repeated. No food or carbonated drink should be allowed until a bowel movement has been obtained. Treatment may be safely repeated in one week. When small children are in a poor physical state or when hookworm infection is complicated with ascariasis, hexylresorcinol crystoids (Crystoids Anthelmintic) should first be administered (see p. 578). This drug will remove about 90 per cent of the ascarids and 75 per cent of the hookworms. After two or three doses

at weekly intervals the number of hookworms will usually be reduced below the level of clinical significance. In the event of an associated whipworm infection it is advisable to give tetrachloroethylene and oil of chenopodium combined in the proportion of 9:1 (see p. 582).

Creeping eruption of hookworm origin may be brought under control by freezing the infected area, especially the growing end, with ethyl chloride spray.

## STRONGYLOIDIASIS

**Etiology.** This infection is produced by the threadworm, *Strongyloides stercoralis*. The delicate, threadlike parasitic females, which are barely visible to the naked eye,

FIG. 179. *Strongyloides stercoralis*. A, Rhabditoid larva,  $\times 310$ ; B, filariform larva,  $\times 120$ ; C, D, anterior and posterior ends of filariform larva,  $\times 640$ . (Craig and Faust: Clinical Parasitology. Lea & Febiger.)

live primarily in the depths of the mucous coat of the intestine, from the pyloric wall of the stomach to the rectum, but for the most part at the duodenal level, where they lay eggs in the tissues. As the eggs filter out to the intestinal lumen, they mature and hatch, setting free the active larvae, which escape into the lumen of the bowel, feed and usually moult once in transit, and are evacuated in the feces. On deposition on the soil in a warm, moist, shaded site, the larvae grow and undergo one additional moult on or before their fifth day in the soil, becoming transformed into the third (infective) stage; or they may undergo one or more free-living cycles before they reach the infective stage.

**Epidemiology.** Strongyloidiasis is relatively common in warm, moist climates, but is occasionally seen as far north as Canada. Exposure results from direct contact of the skin with infected soil, especially where there is a high ground-water level, as in the bayou regions of the Gulf coast of the United States and in tropical rainfall areas.

**Pathology.** The sites and methods of entry of *Strongyloides* into the skin and its migration to the intestine by way of the lungs are essentially the same as in hookworm infection (see p. 584). Occasionally, as these worms escape from the pulmonary capillaries, there is considerable cellular infiltration into the alveoli and bronchioles, but this does not destroy the worms, which continue to grow in the smaller respiratory passages and may even enter the bronchial or tracheal epithelium, where foci of infection are sometimes established. Nevertheless the majority of young worms reach the intestine; the females burrow into the mucosa and, about twenty-six days after exposure, begin to deposit eggs. The continued burrowing of the worms, together with the filtration of their eggs, and the hatching and escape of the larvae contribute to the trauma and frequently to the sloughing of portions of the mucosa. There is, otherwise, a general irritation of the involved mucosa with secretion of excess mucus and impaired absorption of food.

**Clinical Manifestations.** There is only a temporary prickling pain at the sites of entry of the infective-stage larvae into the skin. If the number of larvae migrating through the lungs is appreciable or if some become established in the bronchial epithelium, there may be symptoms of an atypical pneumonia. Owing to the changes in involved levels of the bowel, normal tone and function are lost. There is usually dull or sharp

pain in the epigastric region. There may be a debilitating, unchecked mucous diarrhea or diarrhea alternating with constipation. Dehydration and poor digestion may produce severe emaciation. During the chronic phase the larvae may transform to the infective stage in transit down the bowel and produce internal autoinfection; or they may be responsible for perianal invasion. Cutaneous larva migrans due to perianal autoinfection has been observed in Southeast Asia. Patients with chronic infection are more likely to be constipated than to have diarrhea and frequently have neurotoxic manifestations.

The blood picture at the end of the incubation period is that of a leukocytosis with an eosinophilia of 25 per cent or more. In the chronic stage there is characteristically a neutropenia with a moderate eosinophilia and a monocytosis.

**Diagnosis.** This is based on the detection and identification of larvae in the stool (Fig. 179, A, B) or in material aspirated from the duodenum. A high eosinophilic count suggests the possibility of this infection.

**Prognosis.** The prognosis is fair to good in the recently acquired infection, provided persistent specific treatment is carried out. Absence of eosinophilia is a poor prognostic sign, indicating low resistance.

**Prevention.** This requires sanitary disposal of human feces, treatment of infected persons and care not to expose the skin to polluted soil.

**Treatment.** For years the standard therapy has been oral administration with meals of gentian violet medicinal in enteric-coated Seal-In tablets in 0.012- or 0.03- gm. ( $\frac{1}{8}$  or  $\frac{1}{2}$  grain) sizes. The dosage schedule is 0.01 gm. daily for each year of developmental age, for sixteen days. Vomiting once or twice is not a contraindication to continued treatment. If the infection is not eradicated after two courses of oral therapy, 25 cc. of a 1 per cent solution of the drug may be deposited directly in the duodenum by intubation. If there is proof of pulmonary or other extraintestinal strongyloidiasis, it may be necessary to consider intravenous gentian violet therapy, giving a triply filtered 0.5 per cent solution in an amount not in excess of 20 cc. every other day for two weeks. This method of treatment is not advised except in emergencies. Larvae may be passed for several weeks after treatment, but eventually cease to appear with successful termination of the infection. Frequently patients are refractory to treatment.

In such instances it will be well to determine whether there is a likelihood of internal or perianal autoinfection which is maintaining the infection.

**Dithiazanine**, 3-ethyl-2[5-(3-ethyl-2-benzothiazolinyldene)-1,3-pentadienyl]benzothiazolium iodide, is much more effective than gentian violet in the treatment of strongyloidiasis, especially in chronic infections. It has the added advantages of ease of administration and essentially no side effects. In the adult dose of 200 mg. orally in coated tablets three times daily for five or more days, this agent eradicates *Strongyloides* in up to 89 per cent of instances.

## TRICHINOSIS

**Etiology.** This infection is produced by *Trichinella spiralis*. The adult worms are microscopic and live in the mucous coat of the small bowel, especially at the duodenal level. The females produce living young (larvae) which gain access to the mesenteric venules and lymphatics, migrate through the blood stream and filter out in skeletal muscle, where they become encapsulated in about twenty-one days.

**Epidemiology.** Trichinosis is common among pork-eating populations of the North Temperate Zone, in southern South America and in South Africa. Hogs (occasionally bears) are the source of infection, to which man is exposed by the consumption of infected meat in a raw or inadequately processed state. For this reason young children are less commonly infected than older children and adults. Epidemic outbreaks of trichinosis continue to occur in the United States, frequently as a result of eating pork products from a single heavily infected hog, slaughtered on a farm.

**Pathology.** When meat containing viable trichina cysts is eaten, the cysts become separated in the stomach. In the duodenum the larvae break out of the cyst, burrow into the mucosa, mature in about five days, and mate. The females larviposit for about six weeks. There is inflammation as the excysted larvae enter the intestinal wall and mature. Inflammation continues as the larval progeny migrate through the blood stream and become lodged in the muscular tissues.

**Clinical Manifestations.** Symptoms of acute food poisoning begin within a few hours after ingestion of heavily infected meat and last four or five days, paralleling the entry of the excysted larvae into the

bowel wall and their development into mature worms. During the period of larval migration there are typically intense muscular pains, stiffness and tenderness in the diaphragm, lower extremities and muscles of the throat, causing difficulties in breathing, walking, swallowing and talking. An increasingly toxic condition results in edema, especially around the eyes. During this stage or after encapsulation of the larvae there may be disturbances of the central nervous system (motor, sensory or of the higher centers), depending on the sites where migrating larvae have set up inflammatory reactions. There may also be clinical and electrocardiographic evidence of myocarditis resulting from inflamed tracts in the heart muscle through which the larval worms have passed, but in which they do not encyst.

Beginning with the invasion of the duodenal mucosa and continuing through the weeks of larval migration, there is an elevation of temperature to 99° to 102° F. (37.2° to 38.8° C.) or even higher.

There is an early leukocytosis with eosinophilia, later a leukopenia with eosinophilia and monocytosis.

When the infection is not heavy, there may be few or no apparent symptoms.

**Diagnosis.** During the incubation period and the early migration of the larvae diagnosis can be made only presumptively on clinical and epidemiologic evidence. After the larvae have become encapsulated (after the twenty-first day) the disease may be detected by biopsy of deltoid, biceps or gastrocnemius muscle strips, or by intradermal tests, using a 1:10,000 antigen and doing an immediate reading at twenty minutes and a final one at twenty-four hours. The positive intradermal test should be supplemented by the precipitin test to determine whether the infection is recent (ppt +) or of long standing (ppt -). Many cases are diagnosed only at necropsy, and then merely as an incidental finding.

**Prognosis.** This varies from grave to excellent, depending on the severity of the infection.

**Prevention.** Thorough cooking, or freezing of all pork for at least twenty-four hours, will prevent human infection. Since this is not always done, the cooking of all garbage fed to hogs is a valuable method of prevention.

**Treatment.** There is no specific therapy. Management includes administration of analgesics, abundance of citrus fruit juices

and an ample fluid intake to maintain a good urinary output. If trichinosis is suspected during the first two or three days after exposure, daily saline purges with Glauber's salt (sodium sulfate) may serve to dislodge the young worms before they become embedded in the intestinal mucosa and the females start larvipositing.

## FILARIASIS

**Etiology.** Filariasis is produced by one of several filaria worms, the more important of which are *Wuchereria bancrofti*, *W. malayi*, *Onchocerca volvulus* and *Loa loa*. The adult worms are threadlike objects characteristically coiled up in certain body tissues. *Wuchereria bancrofti* and *W. malayi* inhabit lymphatic vessels and lymphoid tissues; *Onchocerca* adults are immured in fibrous subcutaneous nodules; *Loa loa* migrate through subcutaneous tissues. These worms all produce microscopic snakelike embryos called microfilariae, which eventually migrate through the superficial blood vessels or skin.

**Epidemiology.** *Wuchereria bancrofti* is widely distributed through the tropics in both hemispheres; *W. malayi* occurs in India, the Far East and the Southwest Pacific. *Onchocerca* is found in tropical Africa, in a small area where Guatemala and Mexico are contiguous and in eastern Venezuela. The loa worm is found in tropical Africa.

Microfilariae are picked up by bloodsucking flies and develop to the infective-stage larvae in their thoracic muscles. *Wuchereria bancrofti* and *W. malayi* utilize mosquitoes; *Onchocerca*, species of *Simulium*; *Loa loa*, the mango fly *Chrysops*. After incubation in the appropriate insect host the larvae migrate to the tip of the fly's proboscis and enter the skin of the exposed person in or near the puncture wound made by the fly. In endemic areas children are more commonly infected than older persons.

**Pathology.** The developmental period in Bancroft's filariasis is about a year, but is not definitely known. Indirect evidence indicates that the larvae, on entering the skin, invade lymphatic vessels and may make long migrations through the lymphatic system before they reach the sites where they mature and mate, and the females begin to parturite. During this period, if they lodge for any time in a lymph node and thus block lymph flow, they may produce an acute lymphangitis and associated lymphad-

enitis. At the end of the incubation period the microfilariae discharged by the female appear in the tissues around the parent worms, and within a short time those of *Wuchereria* and *Loa loa* may be found in the blood. Tissue reaction may be temporary during the migration of larvae or adults, but in Bancroft's and Malayan filariasis, there is usually a series of acute episodes of lymphangitis, often with fever, and subsequently fibrosis of the dead or dying parent worms, resulting in more or less permanent blockage of the involved lymphatic vessels. In onchocercosis, fibrosis around the adult worms develops without acute local reaction, but almost invariably with systemic sensitization. In loa infection there is only temporary swelling in the subcutaneous tissues through which the worm is migrating.

**Clinical Manifestations.** In infection with Bancroft's and Malayan filariasis the biologic incubation period may be marked by acute lymphangitis or allergic states. A second period, usually symptomless, begins when microfilariae are first recoverable, one year or more after exposure. Most patients have repeated attacks of lymphangitis, usually with fever. With fibrotic obstruction of lymph flow, elephantiasis gradually develops, and the skin becomes thickened and is deprived of practically all its blood supply. It cracks readily, providing easy entry for secondary pathogens. The subcutaneous tissues are remarkably thickened and consist of a matrix of fibrous tissue in which lymphatic fluid and adipose tissue are locked.

*Onchocerca* adults produce a painless swelling on any site of the body, but particularly at the junction of the long bones and on the temporal and occipital areas of the head. Their microfilariae tend to migrate to the eyeball and optic nerve, causing diminished vision and eventually blindness. *Loa* usually produces only pruritus, but at times there is generalized edema or giant urticaria.

**Diagnosis.** This is suggested by the clinical manifestations, and is confirmed by recovery of the microfilariae in blood at night (*W. bancrofti*, *W. malayi*), in the daytime (*Loa loa*) or in biopsied skin (*Onchocerca*). When parent worms have died and in the biologic incubation period, microfilariae will be absent.

**Prognosis.** The prognosis is variable and depends on the degree of involvement and on the anatomic location of the lesions.

**Prevention.** This is a difficult task and requires control of the breeding of bloodsucking flies which transmit the infection. DDT has provided a moderately effective means of control.

**Treatment.** There is no simple chemotherapy for any filaria infection, although Suramin (naphuride sodium) and Hetrazan (diethylcarbamazine citrate) are efficacious in killing circulating microfilariae and are moderately lethal for adult worms. The individual dose of Hetrazan is 1 mg. per pound of body weight three times daily after meals. Specific treatment of onchocercosis is complicated by the patient's sensitization reaction to the sudden release of metabolites of dying and dead parent worms. In elephantiasis of an extremity a modified Kondeleon operation may be performed, but is only of temporary value. Tight bandaging with turkish towelling forces the lymph into collateral channels, allowing reduction of the lesion and considerable absorption of the elephantoid tissue. In onchocercosis the subcutaneous tumors should be removed as soon as they appear, to lessen the possibility of grave ocular disease. In loiasis the parent

worm is readily removed when it crosses in front of the eye or over the bridge of the nose.

## DRACUNCULOSIS

(DRACONTIASIS)

Dracunculosis is produced by the dragon or Medina worm, *Dracunculus medinensis*, a distant relative of the filaria worms. It is prevalent in India, the Middle East, Africa and, to a less extent, in other areas. The meter-long adult female migrates from the viscera to the skin to deposit living young in fresh water when a small blistered area of the skin produced by the anterior tip of the worm breaks open in contact with the water, as, for example, during bathing or wading. Infection results from drinking or rinsing the mouth with water containing the infected intermediate host, Cyclops. Prevention is not on a practical basis. There is no satisfactory systemic chemotherapy, but an emulsion of phenothiazine, introduced into the skin along the track of the parturient female, causes its death in a few hours and permits its removal by gentle traction.

## Infections Produced by Tapeworms (Cestoda)

Tapeworms are flatworms (Platyhelminthes), invertebrate animals characterized by either a simplified digestive tract or none at all, a protonephridial excretory system, male and female genitalia usually in the same organism (hermaphroditism), no body cavity and, primitively, a ciliated ectodermal covering. Each tapeworm consists of a group of coordinated units as follows: (1) a scolex or "head," provided with suckers and frequently with rostellar hooklets for attachment; (2) a "neck" or region of growth; (3) a series of proglottids or segments, beginning with immature ones arising from the distal part of the neck and becoming increasingly developed and finally gravid in the distal portion of the worm. The entire worm is called a strobila. Each mature proglottid contains a full set of male and female genitalia. The gravid proglottids are storehouses of eggs. Tapeworms have the following stages in their life cycle: egg, embryo, larva, adult.

The important tapeworm infections of man are teniasis (including the larval-stage infection cysticercosis), hymenolepiasis, diphyllbothriasis and hydatid disease. Dog

tapeworm infection occasionally occurs in children who fondle infected dogs or cats. The comparative epidemiologies of these infections are summarized in Table 79 (p. 574).

## TENIASIS

**Etiology.** Teniasis is produced by the beef tapeworm, *Taenia saginata*, and the pork tapeworm, *Taenia solium*. The former has a length of 15 feet or more, contains about 1000 to 2000 proglottids and has a head with four suckers, but no rostellar hooklets. *Taenia solium* seldom attains a length of more than 5 to 8 feet, has less than 1000 proglottids and has an apical ring of rostellar hooklets, as well as four head suckers. The most distal proglottids are gravid and contain fully embryonated eggs which may be passed in feces, but are more commonly excreted in proglottids (Fig. 180) which are detached from the parent worm.

**Epidemiology.** *Taenia saginata* infection is common in beef-eating peoples like the Mohammedans and also occurs frequently in the United States. *Taenia solium* infection

FIG. 180. Gravid proglottids of *Taenia saginata* and *T. solium*, as passed in the feces or as they migrate from the anus, showing differential patterns of uteri. Left, *T. saginata*; right, *T. solium*. (After Faust, in Brennemann's Practice of Pediatrics. Courtesy of W. F. Prior Co.)

occurs most often in eastern and southeastern Europe, is relatively rare in the United States, but is as common as *T. saginata* in Mexico and certain other Latin American countries. Gravid proglottids, discharged in human feces, disintegrate, and the contaminated soil is infective for cattle (*T. saginata*) or hogs (*T. solium*). The larval stage (cysticercus) develops in striated muscle of these animals, and the flesh becomes infective in about three months. Human beings who consume raw or rare beef or pork are liable to infection with the adult worm.

**Pathology.** The larvae are digested out of the meat in the human stomach, become attached in the upper small intestine and, in about three months, develop into mature worms. Although there is slight inflammatory reaction at the site of attachment, the important pathogenic action is toxic, with generalized manifestations. Occasionally obstruction of the bowel may result from a tangled mass of worms or from detached proglottids which become lodged in the lumen of the appendix.

**Clinical Manifestations.** Toward the end of the incubation period there is considerable digestive disturbance, including mucous diarrhea due to the irritative action of the worm's by-products on the intestinal mucosa. There may be false hunger pains, especially at night. When the worm is mature, there

may be no intestinal disturbance, but there may be other manifestations. These include: (1) inconvenience from gravid proglottids which, having migrated from the anus, crawl down the leg; (2) nutritional drain on the patient; (3) appendiceal inflammation from detached proglottids; and (4) neurotoxic manifestations.

Man is also subject to infection with the cysticercus stage of *T. solium* by swallowing eggs in contaminations from his own or another person's intestinal infection. These cysticerci lodge in any tissue, including the brain, the meninges and the eyeball. Involvement of the brain almost invariably ends in a jacksonian type of epilepsy.

The blood picture at first shows a leukocytosis with moderate eosinophilia; later there is a slight neutropenia with monocytosis and, at times, a secondary anemia.

**Diagnosis.** Teniasis can be diagnosed by recovery of typical *Taenia* eggs in the stool, but most patients do not pass eggs in appreciable numbers. Specific diagnosis can be made from a gross examination of gravid proglottids passed in the stool or migrating from the anus. When these are freed of debris and flattened in the fresh condition (not hardened in alcohol or formalin) between two glass slides, it is easy to count the number of main lateral arms of the uterus. In *Taenia saginata* the number is fifteen to twenty-one, in *T. solium*, seven to thirteen (Fig. 180).

**Prognosis.** This is good in intestinal teniasis if the worms are removed. Rarely, acute intestinal or appendiceal obstruction is a hazard. In cysticercosis cerebral lesions create a grave prognosis.

**Prevention.** Teniasis may be prevented by eating only previously frozen or well cooked beef and pork. More fundamental is the sanitary disposal of human feces.

**Treatment.** Oleoresin of male fern (*Aspidium filix-mas*), formerly the drug of choice, and carbon tetrachloride, which is equally satisfactory, are relatively toxic and require hospitalization of the patient. *Quinacrine* (Atabrine) is superior to either in effectiveness and ease of administration and is less toxic.

For treatment with Atabrine the patient should be on a light, nonconstipating diet for the preceding forty-eight hours and should have complete evacuation of the bowels the night before the drug is administered, if necessary by saline purgation with Glauber's salt (sodium sulfate) (adult dose,  $\frac{1}{2}$  ounce

or 15 gm. in a half-glass of water). In the morning on an empty stomach the adult patient takes by mouth five 0.1-gm. tablets of Atabrine with an equal amount of sodium bicarbonate. For children the dose must be reduced in proportion to developmental, not chronologic, age. Two hours later a saline purge is administered. The worm is characteristically passed intact, deeply yellow-orange stained and contracted, but alive. Nausea and possibly vomiting may be anticipated. To reduce these side effects no food or carbonated drinks should be permitted until after a good bowel movement.

## HYMENOLEPIASIS

**Etiology.** Hymenolepiasis is produced by the dwarf tapeworm, *Hymenolepis nana*, and the rat tapeworm, *H. diminuta*. The former is a small worm, only 1 to 2 cm. in length. Its head is provided with four suckers and a crown of rostellar hooklets. *Hymenolepis diminuta* is appreciably larger (20 to 60 cm. in length) and has suckers but no hooklets on the head. The most distal gravid proglottids disintegrate as they become fully ripe, setting the characteristic eggs (Figs. 171, D; 181) free in the small bowel to be evacuated in the feces.

**Epidemiology.** The dwarf tapeworm, *Hymenolepis nana*, is cosmopolitan in distribution, except in cold climates. It is most commonly a parasite of children. Although this species is found in rats and mice, the strains are distinct and are not readily infective for human beings. Human infection with *Hymenolepis diminuta* results primarily from contact with infected rat or mouse fleas. *Hymenolepis nana* infections are common in children in the southern United States, in many countries of Latin America, India and in the Mediterranean area. *Hymenolepis diminuta* infections have been recorded from several countries and from the United States.

FIG. 181. Egg of *Hymenolepis diminuta*,  $\times 500$ . (Craig and Faust: Clinical Parasitology. Lea & Febiger.)

Eggs of *H. nana* passed in human feces are directly infective for man. They hatch soon after ingestion. On reaching the duodenum the escaping embryos bore into the villi, transform into larvae, return to the intestinal lumen, become attached, and grow into adults within a few weeks. Eggs of *H. diminuta* must undergo a period of larval development in certain insects, usually rat fleas. Ingestion of these intermediate hosts is the source of infection for human beings.

**Pathology.** Except in heavy infections, the damage produced is largely toxic. There is suggestive evidence that in continued heavy infections with *H. nana* internal autoinfection occurs repeatedly.

**Clinical Manifestations.** There may or may not be clinical evidence of infection. A single *H. nana* in a child may at times evoke severe manifestations, with irritability, insomnia, loss of appetite and weight, and rarely convulsions. On the other hand, a moderate number in another child may evoke only mild symptoms. There is usually a moderate eosinophilia.

**Diagnosis.** This is made by demonstration of eggs (Fig. 181) in the feces.

**Prognosis.** This is almost always good, provided specific medication is instituted promptly. In heavy infections with *H. nana* the prognosis may be poor, owing to repeated internal autoinfection.

**Prevention.** Dwarf tapeworm infection can be controlled only by the most careful personal and group hygiene and by treatment of all infected persons. Rat tapeworm infection may be eliminated as a human infection by campaigns against rats and mice and by use of DDT in rat runs or in nests to kill rodent fleas.

**Treatment.** See under Teniasis. Hexylresorcinol (Cryptoids Anthelmintic) as administered in ascariasis (p. 578) is moderately efficient and should be tried first in small children because of its low toxicity.

## DIPHYLLOBOTHRIASIS

**Etiology.** Diphyllobothriasis is produced by the fish tapeworm, *Diphyllobothrium latum*, which measures 5 to 30 feet in length and has possibly as many as 3000 proglottids. The head is spatulate and is provided with a pair of longitudinal sucking grooves. The proglottids never become strictly gravid, but discharge immature eggs.

**Epidemiology.** Fish tapeworm infection is prevalent in the lake districts of Minnesota

and northern Michigan, adjacent territory in Canada and in the lake districts of Chile and Argentina, northern, eastern and south-eastern Europe, Russia, Palestine, Syria, Siberia, Japan and Australia. Elsewhere it is rarely endemic, but iced fish shipped from endemic areas are responsible for many cases in other regions. Gefüllte fish may be a source of infection if it is eaten before it has been cooked. The immature eggs passed in feces are broadly ovoidal and operculate (Fig. 171, C). When discharged into cold fresh water, they must incubate for about two weeks, whereupon the shell opens to release a ciliated embryo. This swimming organism is eaten by little water fleas of the genera *Diaptomus* and *Cyclops*, in the bodies of which the embryos transform into proceroid (first-stage) larvae. Fresh-water fish consume the infected water fleas and acquire infection in their flesh, the plerocercoid or sparganum (second-stage) larvae. Larger fish in turn consume the smaller ones and acquire the infection in their muscular tissues. Man, dogs or bears eat the fish in a raw or inadequately processed condition and become infected.

**Pathology.** Fish tapeworm infection frequently produces a toxic state, possibly due to absorption of unsaturated fatty acids, particularly if the worms are attached to the duodenal mucosa, where they prevent absorption of vitamin B<sub>12</sub>.

**Clinical Manifestations.** In addition to the toxic condition, fish tapeworm may be associated with a primary anemia. It is believed that the tapeworm, when attached to the duodenal or jejunal mucosa, precipitates an anemic state in persons having an unstable equilibrium with respect to the antianemic intrinsic factor. There is usually a leukocytosis with eosinophilia, followed in the chronic period by a leukopenia with a monocytosis. At times there is a macrocytic or normocytic hyperchromic anemia.

**Diagnosis.** This is made on recovery of the eggs (Fig. 171, C) in the patient's feces.

**Prognosis.** This is good with specific treatment.

**Prevention.** Thorough cooking of all fresh-water fish would prevent infection. Prohibition of catching fish during the summer months when the fish are heavily parasitized would also reduce the hazard. Basic control consists in sanitary disposal of human excreta, since the reservoir hosts (dogs and bears) probably contribute little to human infection.

**Treatment.** See under Teniasis (p. 590).

## HYDATID DISEASE

(ECHINOCOCCOSIS)

**Etiology.** Hydatid disease is produced by the larval stage (hydatid cyst) of *Echinococcus granulosus* and *E. multilocularis*, minute worms which live as adults in the small intestine of the dog and its wild relatives.

**Epidemiology.** This disease is widely distributed wherever sheep, cattle and hogs are associated with dogs. It is particularly common in man in Australia, New Zealand, Palestine, Syria, Argentina, Uruguay, southern Brazil and Chile. Occasionally autochthonous cases occur in the United States. *Echinococcus multilocularis* is common in the highlands of Central Europe, where foxes replace dogs and wood mice replace sheep, cattle and hogs in the natural evolution of the infection (see below). This cycle also occurs in northern Alaska, Siberia and Japan.

The eggs of *E. granulosus* passed in an infected dog's feces initiate the infection in practically any mammal, except a rodent, which ingests the eggs. These hatch in the duodenum; the escaping embryos bore into the intestinal wall, gain access to mesenteric venules or lymphatics and are carried to various parts of the body where they are filtered out. Dogs become infected from eating the carcasses of animals which have died of the disease. Man's association with infected sheep and cattle dogs and parasitized pet dogs provides the means for exposure to the disease.

**Pathology.** Unless the young larvae lodge in some vital location in the human body, they will develop to a considerable size before their presence is discovered. Thus infection acquired in childhood may not be detected until middle life. Although the little hydatid cyst provokes an acute inflammatory reaction at the site of implantation, it proceeds to vacuolate, to develop its germinative layer with many viable heads (scolices) and to accumulate hydatid fluid within the cavity. The cysts grow slowly, but in several years may reach the size of an orange or grapefruit. They are usually spherical and filled with fluid. The outer layer is essentially a non-cellular laminated structure which is friable; the entire cyst is surrounded by adventitia. The fluid contains considerable foreign protein and is extremely toxic for the host if there is appreciable seepage or if the cyst bursts. Rupture of a cyst may cause anaphylactic shock or may only set free a large num-

ber of viable scolices which become implanted elsewhere and develop secondary cysts. If the cyst reaches the shafts of long bones, it may proceed to grow as a syncytium (osseous hydatid). The most common sites of hydatid cysts in man are, in descending order, the liver, lungs, brain, peritoneal cavity and bone, but no tissues are exempt. The hydatid of *E. multilocularis* is alveolar, without limiting membrane or adventitia, almost invariably develops in the liver, and is essentially malignant in its growth.

**Clinical Manifestations.** If the larva of *E. granulosus* lodges on a heart valve or in the brain or eye, the lesion causes grave symptoms relatively early in the infection. If it develops in the lungs, the first evidence may be a violent paroxysm of coughing with discharge of the contents of a ruptured cyst. If a unilocular cyst is hepatic in location, twenty or more years may pass before the weight of the cystic mass causes sufficient inconvenience to bring the patient to a physician. However, a blow on the abdomen may rupture the cyst and cause death from anaphylactic shock. The hydatid of *E. multilocularis* produces symptoms of hepatic disease. Eosinophilia is proportionate to the leakage from the cyst.

**Diagnosis.** This is difficult before operation. Eosinophilia is suggestive, but depends on leakage from the cyst. Hydatid thrill is suggestive, but difficult to elicit. Serologic tests are the most reliable. These include complement fixation, precipitin and intradermal tests with antigen prepared from sterile hydatid fluid, which is usually obtained from infected sheep.

**Prognosis.** The prognosis of a unilocular hydatid is fair if the cyst is in an operable site. Recurrence from the spilling of scolices from the parent cyst at the time of operation is common. Osseous hydatid disease is serious, and surgical intervention is rarely helpful. In alveolar hydatid disease the prognosis is always grave because the lesion is uncircumscribed.

**Prevention.** Control in endemic areas involves the deep burying of dead sheep and cattle. Periodic deworming of dogs with arecoline hydrochloride in endemic areas greatly reduces the amount of exposure to the eggs. Man must be careful to keep dog feces from contaminating his food, drink or cooking utensils. Children should not be allowed to play with dogs which have access to sheep, cattle or pigs in endemic areas.

**Treatment.** No chemotherapy is available for treating the larval stage of the two species of hydatid infections which occur in man. If the cyst is unilocular and in a favorable location for operation, an incision is made down to the outer cyst wall and the hydatid fluid is aspirated, with care not to spill a drop in the operative area. Then the cyst wall is incised and enough 10 per cent formaldehyde is introduced into the cavity to sterilize the germinative layer. If possible, the entire cyst should be enucleated; if this is not feasible, the cyst should be collapsed and closed with sutures separately from closure of the operative wound. In inoperable cases desensitization with hydatid antigen, as in the treatment of bee allergy, offers some promise of relief.

## Infections Produced by Flukes (Trematodes)

Flukes belong to a group of flatworms (Platyhelminthes) which are comparable to a single mature segment (proglottid) of a tapeworm. They have an incomplete digestive tract and are either unisexual or hermaphroditic. The flukes which parasitize man have a complicated life cycle, with a required development and multiplication in certain species of snails. In some flukes there is also a required second intermediate host in which encystation occurs. The most important fluke infections are the schistosomiasis and those due to the intestinal flukes, the liver flukes and the lung flukes (see Table 79, p. 574).

### SCHISTOSOMIASIS

**Etiology.** This group of diseases is produced by the two intestinal blood flukes, *Schistosoma japonicum* and *S. mansoni*, and the vesical blood fluke, *S. haematobium*. These worms are unisexual and small enough to live as mated pairs in the smaller venules draining the intestine and the urinary bladder. The female, held in the ventral sex canal of the male, deposits a series of eggs which completely fill the venule. Oviposition is repeated in adjacent venules into which the worms migrate, so that entire venous radicles may be crowded with eggs. These

FIG. 182. Egg of *Schistosoma japonicum* as seen in freshly passed feces,  $\times 666$ . (After Faust, in Brennemann's Practice of Pediatrics. Courtesy of W. F. Prior Co.)

eggs are partially embryonated when deposited and soon secrete a lytic fluid which oozes through minute pores in the shell. By pressure on, and digestion of, the wall of the venule the eggs escape into the perivascular tissues and then through the mucous coat of the organ into its lumen, together with extravasated blood. Eggs of the intestinal types are passed in the stool; those of the vesical type, typically in the urine, but at times also in the feces (Figs. 171, E, F.; 182).

**Epidemiology.** The blood fluke infections have an extensive distribution and involve millions of people in endemic territory. *Schistosoma japonicum* occurs in the Orient, especially in central, west and south China; in five foci in Japan and on five of the Philippine Islands; *S. mansoni*, in Africa, Arabia, Puerto Rico, the Lesser Antilles, extensive areas of Brazil, Dutch Guiana and two foci in Venezuela; *S. haematobium*, in Africa, the Near East, Iran, Iraq, western India and the southern tip of Portugal. Children are more frequently exposed than adults.

If eggs evacuated in feces or urine soon reach fresh water, they hatch, and the escaping ciliated larvae (miracidia) are enabled to attack and enter the soft tissues of appropriate species of snails. After development and two consecutive stages of multiplication in the snails, the parasite emerges in the fork-tailed larval stage (cercaria) and swims in the water, but eventually dies unless it infects man or certain other mammals.

**Pathology.** When man invades infected water, the blood fluke larvae attach them-

selves to his skin. They enter cutaneous blood vessels, producing slight injury, are carried to the lungs, gradually squeeze through the capillaries, and most are returned to the systemic circulation. Some larvae break out of the pulmonary capillaries with resultant petechial hemorrhage. The larvae which arrive by way of the mesenteric arteries in the portal blood stream feed on whole blood, grow and then migrate back into the mesenteric venules against the incoming portal blood. *Schistosoma japonicum* enters the drainage of the small bowel; *S. mansoni*, that of the large bowel; and *S. haematobium* migrates through the rectal and hemorrhoidal veins into the vesical venous plexus. Here the worms mature and mate, and the females begin to lay eggs. The approximate incubation periods are, for *S. japonicum*, four to five weeks; for *S. mansoni*, six to seven weeks; and for *S. haematobium*, ten to twelve weeks.

During the incubation period, as the larval worms reach capillaries through which they cannot pass and where they perish, or as they rapidly increase in size in successful locations, an increasing amount of toxic metabolites is distributed throughout the patient's body, in particular among the tissues and organs in the immediate vicinity of the worms. Then, as eggs are laid, there is initially extensive traumatic damage as they escape from the blood vessels and filter through the tissues. Later, pseudoabscesses form around eggs which become lodged in the perivascular tissues. These lesions usually are transformed into pseudotubercles.

**Clinical Manifestations.** At each site of invasion of the skin by the cercariae there is a minute lesion with sharp needling pain which lasts only a few hours. As the larval worms pass through the lungs and later lodge elsewhere, there is considerable local and generalized reaction, particularly in the liver, which becomes greatly enlarged and tender, and on the skin as giant urticaria. Toward the end of the incubation period there are late afternoon fever and night sweats. In the intestinal types there is a prodromal toxic diarrhea. Then, with the discharge of eggs, there is an accompanying dysentery (*S. japonicum*, *S. mansoni*) or hematuria (*S. haematobium*). The patient usually becomes acutely ill and, in the intestinal types, bedridden. After a few weeks of rest the dysentery is arrested, but on physical exertion is reactivated. Digestive disturbances are increased as fibrosis of the intestinal wall develops, while papillomas and cicatricial tissue

prevent the normal passage of food or feces. The liver shows signs of periportal cirrhosis, the spleen becomes greatly enlarged, and the thoracic cavity is reduced in capacity as a result of the increase in size of the abdominal viscera. In the vesical type the urinary bladder gradually becomes thickened, fibrosed and infiltrated with phosphatic salts. Renal colic is caused by bladder stones produced by deposition of uric acid crystals on the eggs as nuclei. In the intestinal types, ascites develops in the late chronic stage. In the vesical type there is incontinence of urine. In both varieties of schistosomiasis, sepsis may be anticipated in the chronic stage, and carcinoma of the liver, intestinal wall or urinary bladder may develop as a result of constant irritation.

During the acute stage there is a pronounced eosinophilia. Later there is a neutropenia with a moderate eosinophilia and monocytosis.

**Diagnosis.** This is made by recovery of the typical eggs in the stool (*S. japonicum*, Fig. 182; *S. mansoni*, Fig. 171, E) or in the urine (*S. haematobium*, Fig. 171, F).

**Prognosis.** This is fair to excellent in the acute or early chronic stages with specific therapy, but is poor in long-standing, inadequately treated chronic infections. In highly endemic areas, as in China, the Philippines and parts of Egypt and Brazil, children who are repeatedly subjected to heavy exposure die of the disease before reaching maturity.

**Prevention.** The use of copper sulfate or newer molluscicides such as sodium pentachlorophenate (Santobrite) in "infected water" to kill the snails which are intermediate hosts and prohibition of wading or bathing in suspected water are temporary and relatively inadequate measures. Permanent control can be effected only by sanitary disposal of human excreta. In endemic areas of *S. japonicum* infection the control problem is complicated by many mammalian reservoir hosts which can perpetuate the disease in the absence of human infection.

**Treatment.** Antimony salts are specific. Sodium antimony tartrate and potassium antimony tartrate (0.5 to 2 per cent solutions) are the drugs most likely to be effective in a single course of treatment, but their toxicity should be appreciated. The antimonials are introduced slowly into a vein, with care not to allow a single drop to escape into perivascular tissues and so cause painful necrosis. The patient must be recumbent during the period of administration and for at least a

half hour thereafter. The drug is administered three times a week for four to twelve weeks, beginning with 6 cc. and increasing to a tolerance of 20 cc. of the 0.5 per cent solution in adults with a weight of 50 kg., with proportional reductions for children.

Fuadin (stibophen), another antimony compound, is better tolerated and more easily administered than the antimony tartrates, since it is introduced intramuscularly and is more slowly absorbed, but its efficiency is considerably less, and treatments frequently must be repeated. The drug is administered as a 6 per cent solution three times a week. The first and second injections consist of 1.5 cc. and 3.5 cc., respectively, and are followed by nine ampules of 5 cc. each. These dosages are for adults, but may be given to children nine years of age or older. Fractional doses should be given to younger children.

Miracil D, which is administered orally, has been used with some success for *S. haematobium* infection, but is ineffective for intestinal schistosomiasis.

In advanced chronic cases specific treatment is useless because of the irreparable tissue damage.

**Cercarial (Schistosome) Dermatitis.** The cercariae of human blood flukes do not produce "swimmer's itch." Swimmer's itch, or

FIG. 183. Papular eruption of leg in cercarial dermatitis (swimmer's itch) acquired in a Michigan lake. (After Dr. D. B. McMullen, Army Med. Graduate School, from Mackie, Hunter and Worth: Manual of Tropical Medicine.)

"cercarial dermatitis," is caused by penetration of cercariae of blood flukes which are not able to complete their development in the human body. These are usually blood flukes of aquatic birds, occasionally of passerine birds or of domestic mammals. "Cercarial dermatitis" is widely distributed through the world, including the lake districts of the northern United States and both fresh- and salt-water areas along the east and west coasts. These cercariae on entry into the epidermis are not able to get into the cutaneous blood vessels, and their presence causes a pruritic dermatitis (Fig. 183). Children are highly susceptible, and are exposed especially during their vacation months.

## INTESTINAL FLUKE INFECTIONS

### (INTESTINAL TREMATODIASIS)

**Etiology.** Several groups of trematodes inhabit the intestine of man. These include *Fasciolopsis buski*, the giant intestinal fluke, which is fleshy and measures 20 to 75 mm. in length by 8 to 20 mm. in breadth; several species of echinostomes, which have a cervical collar of toothlike spines and vary in size from 0.5 to 20 mm. in length by 0.1 to 2.5 mm. in breadth; and the heterophyid species, which superficially resemble small seeds. These worms are most frequently attached to the duodenal and jejunal mucosae. Their eggs are operculate and vary in size from 140 by 85 microns (*F. buski*) to 28 by 16 microns (heterophyid species).

**Epidemiology.** *Fasciolopsis buski* has an extensive distribution in the Far East, southeast Asia and eastern India. It is contracted from the consumption of raw water plants such as the "water chestnut" and "buffalo nut," on which its larval stage is encysted. Echinostome species are found in the Far East, India and occasionally in the Balkans; infection with these species results from eating raw plant and animal tissues. Heterophyid species are present in the Orient, Egypt and the Balkans; they reach the human intestine in raw or inadequately cooked fresh-water and brackish-water fish. Some of these species occur commonly in reservoir hosts.

**Pathology.** The adult worms, especially the larger species, tend to erode the intestinal mucosa at the site of attachment. Moreover, their by-products are absorbed. Heterophyid flukes provide an additional grave hazard. Their minute eggs may get into the mesenteric lymphatics and venules and

be carried to various organs where they cause small pseudotubercle formations.

**Clinical Manifestations.** When the adult worms of the larger species attach themselves to the intestinal mucosa, they provoke intestinal disturbances, including a more or less serious mucous diarrhea. Their by-products, when absorbed, cause edema (especially around the eyes), ascites and even anasarca. These symptoms are frequently noted in children, the age group most commonly infected. When the minute eggs of the heterophyid flukes lodge in the heart muscle, they provoke a myocardial disturbance similar to that of beriberi; in the central nervous system they cause embarrassment to motor and sensory functions.

**Diagnosis.** This is made by recovery of the particular type of egg from the feces.

**Prognosis.** This is good to excellent with specific anthelmintic medication, except in heterophyid infections in which eggs have infiltrated into critical centers.

**Prevention.** There are few data on prevention. Control is particularly difficult, since these parasites exist in many reservoir hosts. Thorough cooking of all foods would provide a safeguard, but this is not feasible in many endemic areas.

**Treatment.** Tetrachloroethylene, as administered in hookworm infection (p. 585), and hexylresorcinol crystoids (Crystoids Anthelmintic), as administered in ascariasis (p. 578), are safe, efficient drugs.

## LIVER FLUKE INFECTIONS

### (HEPATIC TREMATODIASIS)

**Etiology.** The important liver flukes which parasitize man are *Fasciola hepatica*, the sheep liver fluke; *Clonorchis sinensis*, the Chinese liver fluke; and *Opisthorchis felinus*, the cat fluke. *Fasciola hepatica* is a moderately large species which lives in the proximal bile passages and the gallbladder. *Clonorchis* and *Opisthorchis* are delicate, lanceolate species which inhabit the bile ducts. *Fasciola* lays large eggs (140 by 75 microns) practically indistinguishable from those of *F. buski*. Eggs of *Clonorchis* measure 29 by 16 microns, and those of *Opisthorchis* 30 by 11 microns. These eggs are transported in bile and are evacuated in feces.

**Epidemiology.** *Fasciola hepatica* exists wherever sheep are raised and is an important parasite in these and other herbivorous mammals. Human infections are comparatively

few, but there are several hundred authentic records, many from Latin America and southern France, and several from Hawaii. Man frequently acquires *Fasciola* infection from eating raw water cress. Clonorchiasis is common throughout the Orient; opisthorchiasis is prevalent in eastern and southeastern Europe, Russia, including Siberia, and French Indochina. They are acquired by man and other mammals that eat raw fresh-water fish. A related species of *Opisthorchis* (*O. viverrini*) occurs in northern Thailand.

**Pathology.** On consumption of food containing the encysted larvae and their passage into the duodenum, excystation occurs. The larvae of *Fasciola* migrate through the bowel wall, traverse the peritoneal cavity, penetrate Glisson's capsule and burrow through the hepatic parenchyma to the larger bile ducts. They produce extensive damage en route through the liver. The larvae of *Clonorchis* and *Opisthorchis* migrate through the ampulla of Vater to the smaller bile ducts. Man is usually infected with a relatively small number of *Fasciola*, but several hundred to a few thousand of *Clonorchis* and *Opisthorchis* may accumulate over a period of years. Occasionally *Fasciola* larvae en route from the duodenum to the bile ducts via the peritoneal cavity lodge and develop in ectopic foci, as in the abdominal wall.

**Clinical Manifestations.** When the worms are established and mature, they provoke a hyperplasia of the biliary epithelium, followed by fibrotic encapsulation of the duct and eventually by pressure necrosis of the parenchyma, occasionally terminating in periportal cirrhosis. The most frequent symptoms are those of cholecystitis and cholelithiasis.

**Diagnosis.** This is made by recovery of the eggs from feces or by biliary drainage. The latter method is more reliable in view of the close resemblance of all these eggs to those of intestinal trematodes.

**Prognosis.** This is fairly good in less heavily infected cases in which liver function is usually not seriously impaired.

**Prevention.** The only practical prophylactic measure is thorough cooking of salad greens and fresh-water fish.

**Treatment.** Emetine hydrochloride (6 per cent solution), administered in the amount of 0.036 gm. ( $\frac{3}{5}$  grain) intramuscularly daily for nine to twelve days, is fairly satisfactory for removing *Fasciola*, and in this dosage is relatively safe. Gentian violet medicinal, as recommended in strongyloidiasis (p. 586), is lethal for *Clonorchis* in early

infections before fibrosis of the bile ducts occurs, but is of little value in old infections.

## LUNG FLUKE INFECTION

(PULMONARY TREMATODIASIS)

**Etiology.** The only fluke which produces pulmonary infection in man is *Paragonimus westermani*. This is a fleshy little worm somewhat resembling the kernel of a hazelnut. The eggs are broadly ovoidal, dark golden brown, have a relatively flat operculum, and measure about 90 by 55 microns.

**Epidemiology.** *Paragonimus westermani* is widely distributed through the Orient and the Southwest Pacific islands, and has been found in isolated regions of Colombia, Ecuador and Peru. Man, cats and dogs are exposed to infection when they eat raw or inadequately pickled crab and crayfish meat in infected areas. On arrival in the duodenum the larvae excyst and migrate through the intestinal wall, traverse the peritoneal cavity, bore through the diaphragm and reach the lungs by way of the pleural cavity. They migrate to sites near bronchioles and provoke tissue encapsulation. In addition, there are numerous instances of these worms in nonpulmonary tissue, particularly the brain, abdomen, groin and neck.

**Pathology.** In the lungs the worms become partly walled off, but invariably have an opening into an adjacent bronchiole. Frequently blood vessels extend into the lesion. The eggs escape into the bronchiole and are coughed up, at times with blood.

**Clinical Manifestations.** In pulmonary infections there is excessive bronchial secretion which may have a rusty brown color, owing to the presence of eggs. Hemoptysis may occur. In the abdomen the worms typically provoke abscess formation; in the groin, a small hard tumor; in the brain they produce lesions responsible for a jacksonian type of epilepsy, a condition common in infected children in Japan.

**Diagnosis.** Pulmonary infection requires differentiation from tuberculosis and other pulmonary diseases. The diagnosis is established by identifying the eggs in the sputum or, when swallowed, in the feces. Though this worm may be suspected as the cause of symptoms in other areas of the body, specific diagnosis depends on operation or on post-mortem examination.

**Prognosis.** This is fair to good in pulmonary infection, fair in abdominal or groin involvement, and grave in cerebral infection.

**Prevention.** No effective control has been developed, but thorough cooking of crabs and crayfish would safeguard human beings.

**Treatment.** There is no satisfactory treatment, but emetine hydrochloride, given as in liver fluke infections, may help.

## *Arthropods as Causative Agents and Transmitters of Disease*

The role of arthropods (i.e., insects and their allies) in the production of disease is three-fold: (1) Certain arthropods elaborate venoms which they introduce into the human body; (2) certain arthropods are tissue invaders; (3) many arthropods are mechanical transmitters of pathogenic microorganisms, and more are obligatory incubators and transmitters of disease-producing microorganisms.

### VENENATING ARTHROPODS

This group of arthropods includes centipedes, scorpions, spiders, ticks, mites and several species of insects.

**Centipedes.** These animals have a pair of hollow jaws which serve as fangs to introduce into the skin toxic substances elaborated in their heads. The venom is relatively weak and at most, even in an infant, will produce an inflammatory reaction at the puncture site and mild lymphangitis. It may be treated with local compresses of magnesium sulfate.

**Scorpions.** Many species of scorpions, including the dangerous ones in the southwestern United States, Latin America, North Africa, southern Europe, and India, have potent venom. This is elaborated in the swollen caudal segment and is introduced through the sharp, hollow caudal extremity into the skin of a person who accidentally steps on the animal or unconsciously brushes it with the arm.

The venom of some species produces only local tissue reaction, while that of other species is primarily neurotoxic in its action. Such venom contains several fractions, including hemolysins, endotheliolysins and neurotoxins. In addition to an intense, aching pain, radiating from the site of the injury, and lymphadenitis, there is typically an ascending motor paralysis, with convulsions resembling those observed in strychnine poisoning, rapid weak pulse, extreme thirst, and dysuria; at times there is evidence of an acute pancreatitis. Deaths from scorpion stings occur particularly in children under four years of age. In most countries where the more dangerous species are common, standardized species-specific or group-specific

antivenin is available for intramuscular administration.

Supportive treatment consists in parenteral administration of glucose and amino acid solutions. Shock should be treated with parenteral solutions, including blood plasma. Morphine is not indicated. Such patients can be controlled effectively by phenobarbital. Relatively large doses of sodium phenobarbital are necessary for irrational patients and those with convulsions. For example, 120 mg. (2 grains) of sodium phenobarbital are injected subcutaneously initially in infants and children up to twelve years of age; subsequent doses of similar amounts are given at intervals of twenty or thirty minutes up to four or five administrations. Epinephrine is given for the temporary relief of hypotension.

The application of residual sprays of DDT in and around homes and outbuildings where scorpions hide will greatly reduce their numbers.

**Spiders.** All spiders produce venoms to stun or kill their prey, but relatively few species have powerful enough fangs or potent enough venom to endanger human beings as does the black widow spider, *Latrodectus mactans*. When her web is accidentally touched by the unprotected human body, this spider attacks. She strikes with her fangs and inserts them deeply into tender skin. There is an immediate sharp pain at the site, with a burning, swollen, inflamed area surrounding the puncture wound. The venom enters the blood stream and produces dizziness, weakness, tremors, abdominal cramps and typically a spastic contraction of the muscles, particularly of the abdomen. There is rapid shallow respiration, tachycardia and high arterial blood pressure. Acute nephritis may develop as a result of the intoxication. Hemoglobinuria has been reported in small children. The double fang markings at the site of inoculation may provide a diagnostic clue, but diagnosis is usually made from the clinical history.

Treatment consists in intramuscular injection of standardized species- or group-specific antivenin if available. Pain can be reduced by the intravenous injection of 10

cc. of a 10 per cent solution of calcium gluconate. Barbiturates may be needed to allay muscle spasm and pain. Neostigmine bromide, U.S.P., may also be used to reduce spasms of smooth muscle. Most of the reported deaths have occurred because the patients were brought to the hospital too late for supportive or antivenin treatment.

Species of the hairy brown genus *Loxosceles*, which are domestic in their habitats, produce *necrotic arachnidism*. *L. laeta* and *L. rufipes* in South America cause topical necrosis and at times systemic hemolysis. In Missouri, Kansas and the southwestern United States the species *L. reclusus* is relatively common in closets, cellars and outbuildings. It is not aggressive, but when crushed or entangled in clothing both the male and the female bite, causing severe local pain, with rapid development of a thick wheal which transforms into a violaceous sloughing ulcer, leaving a deep granulating base. Healing takes place slowly. Within twenty-four to thirty-six hours after the bite systemic reactions consisting of restlessness, fever and at times a scarlatiniform rash are observed. Experimentally, the venom has been found to contain a powerful necrotoxin.

Ten per cent DDT in kerosene sprayed on the spider's web is lethal to the spider.

**Ticks and Mites.** Many species of ticks and several species of mites cause serious local irritation at the sites on the skin where they take blood meals. The most notorious mites are the chigger ("red bug") and the rat mite. These are particularly irritating for small children. The local lesion at the site of attachment can be effectively treated by application of phenolated camphor solution in pure mineral oil or Quotane ointment (containing 1[ $\beta$ -dimethylaminoethoxy]-3-*n*-butylisoquinoline hydrochloride). Dusting of DDT into socks and pants, or rubbing of dimethyl phthalate on the ankles and legs, will usually prevent infestation with these mites.

Certain ticks, as the Rocky Mountain wood tick, introduce saliva which may produce a flaccid ascending motor paralysis which begins in the lower extremities. Recovery is usually rapid and complete if the tick is removed quickly, but if it is allowed to remain, death may result from respiratory paralysis.

**Insects.** These include bees, wasps, ants, blister beetles, moth caterpillars and many bloodsucking insects. The honeybee worker introduces her stinger along with venom; the bumblebee retains her stinger. Bees, wasps and ants have both acid and alkaline frac-

tions as well as a histamine-like fraction in their venom. The stinger must be removed carefully after honeybee venenation. Hypersensitive persons who go into shock require prompt use of epinephrine, and then should be desensitized with whole bee extract made up in Coca's solution to minimize subsequent reactions.

Blister beetles produce a painful blister when their juices are brought in contact with the skin. Ammonia will partly neutralize the blister fluid, and calamine lotion will ease the pain. Certain caterpillars elaborate venom at the base of some of their hairs. When these hairs come in contact with the skin or mucous membranes, they produce a painful burn which heals slowly. The pain is partially eased by calamine lotion.

Many insects, such as mosquitoes, stable flies, fleas, lice and assassin bugs, introduce saliva into the skin before taking a blood meal. This foreign protein produces allergic manifestations in many persons. Since no method of treatment is eminently satisfactory, such hypersensitive persons must learn to protect themselves from these insects.

## TISSUE-INVADING ARTHROPODS

Among the arthropods which invade tissues the following are important: the itch mite (*Sarcoptes scabiei*), which produces scabies; the chigoe (*Tunga penetrans*); and the maggots or larval stage of many species of filth flies and their relatives, which cause myiasis.

**Scabies.** This disease, produced by *Sarcoptes scabiei*, is cosmopolitan in distribution and is most frequently found in lower economic groups whose personal hygiene is neglected. The adult mite is an eight-legged organism which burrows into the deeper layers of the skin and forms a tunnel nearly parallel to the surface. At the blind end of the tunnel the female lays about ten eggs a week for four or five weeks. In three to five days the eggs hatch, and six-legged larvae emerge. These young mites either make lateral tunnels or come out of the tunnel and form new ones. Since an entire life cycle may be completed in eleven to fifteen days, an infestation, once established, develops rapidly. The tunnel appears superficially as a slightly raised, reddened, somewhat sinuous track. (See page 1294 for clinical discussion.)

**Chigoe Infestation.** *Tunga penetrans*, a flea, is a common skin parasite of dogs, pigs and bare-footed persons in the American tropics and tropical Africa. The most common

sites of infestation are the spaces between the toes, into which the fleas burrow. The females swell to the size of a pea and produce painful, festering lesions. The gravid fleas should be removed with a sterile needle and the wounds painted with tincture of iodine to kill the remaining fleas and eggs. Since infestation is usually acquired from direct contact of the bare foot with dust or dirt harboring fleas from the feet of dogs or pigs, well-shod feet practically guarantee safety from attack.

**Myiasis.** This results from penetration of animal tissues by the larval stage of several species of flies. It may be specific, semispecific or accidental, depending on the species of fly. Myiasis may affect the skin, eye, nasopharynx, ear, intestine or urethra.

Specific myiasis refers to a natural tendency of the gravid fly to deposit eggs or larvae on unbroken skin or uninjured mucous membranes. Certain species, such as the tropical warble fly (*Dermatobia hominis*), the sheep bot (*Oestrus ovis*), the cattle bots (*Hypoderma* species), the horse bots (*Gasterophilus* species) and the primary screwworm (*Callitroga hominivorax*) are myiasis-producing forms.

Semispecific myiasis-producing species are those which deposit their eggs or larvae either on or in clean or ulcerated tissues. These include the flesh flies (*Sarcophaga* species, *Wohlfahrtia* species) and the common American screwworm (*Callitroga macellaria*). Both groups produce mutilating wounds, which consist of long, serpiginous tunnels under the skin (larva migrans), deep wounds more or less perpendicular to the surface, or excavating lesions which become secondarily infected. Children are the most frequent victims. Death may occur and be due to extensive deep penetration into the lungs, brain or abdominal viscera.

The third type of myiasis is purely accidental, and consists in the implantation of eggs or maggots in wounds, or their temporary lodgment in the intestine or urethra.

Maggots burrowing into tissues or breeding in wounds should be removed as soon as possible. The lesion should be irrigated, bacitracin applied, and covered with a sterile dressing. In intestinal myiasis frequent saline purgation and enemas may be helpful. Young children, particularly those around stock farms, should be protected from flies by screening or mosquito netting, and any discharges from the eyes, nares or skin lesions should not be allowed to accumulate, since

these attract myiasis-producing flies. Permanent control consists in eradication of breeding by these flies, especially around cattle, horses, hogs and domestic rabbits.

## ARTHROPODS AS TRANSMITTING AGENTS OF DISEASE

Arthropods serve in two ways to transmit disease-producing microorganisms to man: (a) mechanically and (b) as essential biologic hosts or incubators of pathogens.

**Mechanical Transmitters.** The most important group of mechanical transmitters is that of the filth flies, including the common housefly, the lesser houseflies, stable flies, greenbottles, bluebottles, blowflies, the flesh flies, the hover flies, fruit flies and the cluster flies. They are responsible for the transmission of typhoid and other salmonella infections, cholera and amebiasis. Evidence is less conclusive that they play a conspicuous role in the spread of poliomyelitis and epidemic conjunctivitis.

**Essential Transmitters.** Arthropods which are biologic vectors of pathogens include (1) the ticks, which transmit tick spotted fever, Q fever, Colorado tick fever, relapsing fever and tularemia; (2) red mites, which transmit scrub typhus, and mouse mites, which transmit rickettsialpox; (3) lice, which transmit epidemic typhus fever, trench fever and relapsing fever; (4) fleas, which transmit plague, murine typhus and several other infections; (5) mosquitoes, which transmit malaria, yellow fever, dengue, encephalomyelitis, filariasis and tularemia; (6) sand flies, which transmit kala-azar, cutaneous and mucocutaneous leishmaniasis, Oroya fever and pappataci fever; (7) *Glossina* flies, which transmit African trypanosomiasis; (8) black gnats, which transmit onchocercosis; and (9) assassin bugs, which transmit Chagas' disease.

Children are particularly susceptible to all these diseases. In some instances protection can be afforded by vaccine, as in yellow fever, Rocky Mountain spotted fever and typhus fever. In some, individual prophylaxis consists in avoiding endemic territory. In certain diseases the only practical safeguard consists in dusting the exposed person's clothing with DDT or using this insect toxicant as a residual spray. One or both of these procedures have been effective in the control of epidemic typhus fever, malaria and filariasis. Another method of attack is the destruction of the reservoir host (i.e., rats in the case of plague

and murine typhus). These arthropods are man's greatest enemy and today constitute his most serious challenge.

## Tropical Eosinophilia

Unusually high, persistent or recurrent eosinophilia in the absence of a readily detectable cause suggests an occult helminth infection. A number of such infections are more or less well known. Trichinosis, visceral larva migrans, cryptic filariasis and sparganosis are all helminth infections in which eosinophilia may be conspicuous while the causative worms are inconspicuous and difficult to detect. Certain of the helminths, whose presence in the adult stage is easily detected by finding eggs or larvae in the feces, sputum or blood, are hidden in the tissues during some stage of larval development when they too may produce high, but transient, eosinophilia. Common examples are *Ascaris* and hookworms, which characteristically produce transient pulmonary infiltration and eosinophilia (Loeffler's syndrome) during the period of larval migration through the lungs.

In tropical countries, particularly in India and other southeastern countries of Asia, there occurs a syndrome known as tropical eosinophilia. It occurs more frequently in

adults than in children. This syndrome is hard to distinguish from eosinophilias resulting from hidden helminth infections; indeed, tropical eosinophilia is not at this time a clearly defined disease entity. In addition to hypereosinophilia, the outstanding features of tropical eosinophilia are chronic or recurrent bronchial asthma and pulmonary infiltration (eosinophilic lung), both of which are relieved by administration of organic arsenicals. Favorable response to arsenotherapy has been regarded as an essential diagnostic feature. It is now evident that diethylcarbamazine, given orally in daily doses of 12 mg. per kilogram of body weight in three divided doses for four days, is equally effective in relieving symptoms and in reducing eosinophilia to normal levels. Owing to its greater safety and ease of administration, it is replacing arsenicals.

The etiology of tropical eosinophilia is unknown. Observations just reported strongly suggest involvement of one or more undetermined species of filarial worms, but the relation of tropical eosinophilia to visceral

larva migrans and pulmonary ascariasis is not clear.

## PROTOZOAN DISEASES

### MALARIA

The clinical vagaries attributed to malaria are more frequent in children than in adults. Only by an understanding of the variations in malarial infections can one explain what takes place in the individual patient.

Malaria is usually described as an infection with one of four species of protozoan parasites, termed "plasmodia." Though such a distinction exists, for practical clinical and diagnostic purposes, malaria may be regarded simply as *two* diseases: One disease, caused by *Plasmodium falciparum*, is potentially dangerous and sometimes fatal; it can produce a fantastic variety of clinical manifestations, but fortunately is readily cured.

The other disease, caused by *P. vivax*, *P. malariae* or *P. ovale*, is more paroxysmal and almost never fatal. It may recur weeks after an adequately treated primary attack in contrast to falciparum infections, which, in the absence of reinfection, rarely if ever recur after adequate treatment.

Thus the term "malaria," when used to identify a particular infection, should be preceded by an adjective which indicates the species of parasite involved. The old term "quartan" is used in reference to *P. malariae* infections. Otherwise the species names (falciparum, vivax and ovale) are used. *Ovale* malaria is exceedingly rare and seldom severe.

**Etiology. Pre-erythrocytic phase.** A malarial infection of any species is acquired when a previously infected female anopheles mosquito injects, with her saliva during the act of biting, tiny organisms called *sporozoites*. These sporozoites reach the sinusoids of the liver through the circulating blood and enter the cytoplasm of hepatic cells. Growth and nuclear division are rapid for some days with formation of small cysts containing hundreds or thousands of *merozoites*. These merozoites are similar to those of the same name which later result from development of the asexual forms in the red blood cells. It is at this stage that the falciparum infection first differs from the others.

At the end of approximately *six days* of development in the liver the falciparum cysts rupture, and many of the liberated merozoites enter red blood cells in the liver sinuses. In vivax infections the development

in the liver requires *eight days*, and some of the merozoites enter hepatic cells to pave the way for a relapse at a later date. The pre-erythrocytic stage of *ovale* has been proved to be *nine days*. The same phase of quartan malaria is estimated to be *nineteen days*.

**Erythrocytic phase.** Irrespective of species, the merozoites which invade red blood cells immediately begin to feed on hemoglobin and to grow. In stained thin blood smears they appear first as tiny signet rings of bluish cytoplasm with a dot of red chromatin (young trophozoite). As they become larger, variable amounts of yellow-brown hematin appear (later trophozoite). The shape may vary during growth until a round organism containing pigment almost fills the red blood cell. The mature parasite (early schizont) stops feeding, and its nucleus divides first in two and finally into eight or more pieces. The cytoplasm arranges itself around the new nuclei, the pigment aggregates into large clumps, and the completed *schizont* or segmenter contains eight to thirty merozoites similar to those formed in the liver. After a specific time the invaded erythrocyte ruptures, and naked merozoites, pigment and erythrocytic debris are freed in the plasma, where the merozoites which fail to enter fresh erythrocytes are phagocytized. Thus an asexual cycle is begun each time a new crop of merozoites invades red blood cells. Only the erythrocytic cycle occurs in infections induced artificially by injection or accidentally as in the transfusion of infected blood.

Malarial parasites are always intracellular except briefly during the transfer from one host cell to another. The malarial paroxysm does not take place until enough cycles have occurred to produce the amount of parasitic material, pigment and red cell debris required to induce febrile or other reactions.

Some of the growing parasites fail to divide. They require about the same time for maturation, but their nucleus remains intact. They become male or female forms which within the red blood cells continue to circulate in the blood stream for a number of days, after which they degenerate and disappear. These forms, called *gametocytes*, are the only forms capable of infecting the mosquito. Gametocytes never degenerate simul-

taneously in sufficient numbers to cause symptoms.

**Mixed infections and broods.** Although mixed infections with two species undoubtedly occur, one species almost invariably is responsible for the clinical picture. Falciparum strains usually dominate vivax, and vivax dominate quartan; only when sufficient immunity is developed to the dominant strain does the other one reach clinical status.

In an infection with a single species distinct broods may develop. Since the liver merozoites are not released simultaneously and the erythrocytic schizonts do not all rupture at the same time, some groups of new parasites begin their existence in red blood cells before or after the majority. When some which are about twelve hours ahead and others about twelve hours behind the majority mature about the same time, their numbers are frequently sufficient to produce an independent reaction, and a new brood is clinically evident. Dominant broods survive, and the others quickly disappear. In vivax or falciparum infections single broods will produce a febrile reaction every other day, whereas, if two broods develop, there will be daily paroxysms. Two broods of the quartan species can be responsible for fever two days out of three, but three broods are required for daily temperature rises. The impossibility of a "species" diagnosis on clinical grounds is apparent.

**Epidemiology.** Only in regions where people, especially children, have gametocytes within their red blood cells can the Anopheles mosquitoes become infected. These areas are chiefly tropical. The United States is now free of indigenous malaria, but infection of local mosquitoes can occur from infected persons.

When breeding of Anopheles mosquitoes is prevented, where the adult mosquitoes are kept from contact with man by screens or nets, or where adult infected mosquitoes are killed by natural enemies or insecticides before the sporozoites have had time to mature, infection of man does not occur. At present no drugs are known which can, with certainty, prevent invasion of the sporozoite, but some which may be toxic can stop the pre-erythrocytic development. Currently available drugs suppress chiefly the erythrocytic forms; when such suppression is effective, clinical disease is not manifest.

The term "congenital disease," as used for syphilis, does not apply to malaria, since merozoites or sporozoites, unlike spirochetes,

cannot pass the intact placental membrane. Only if infected maternal red blood cells mingle with red blood cells of the fetal circulation can infection of the fetus result. Severe falciparum infections of the pregnant woman may damage the placenta, resulting in death of the fetus or premature birth. Malarial infections rarely develop after antepartum or intrapartum separation of a part of the placenta even though the mother is infected at the time of delivery. However, the blood of newborn infants in malarial areas should always be examined for malarial parasites if the infants appear ill. Thus if a special diagnostic term were to be used, "neonatal malaria" would seem better than "congenital malaria." On the other hand, infants born during or shortly after an attack of malaria in the mother appear to acquire a natural infection more slowly than do infants born of healthy mothers. This apparent passive immunity may represent the suppressive effect of a diet consisting solely of milk on vivax malaria, and fetal hemoglobin may be less attractive to the falciparum parasite.

**Pathology.** In all malarial infections there is destruction of red blood cells; the extent depends upon the duration and severity of the infection. Thus the greatest concentration of malarial pigment is in the spleen, liver and bone marrow. At first the spleen shows congestion, then hyperplasia and sometimes necrosis of the follicles with tremendous amounts of pigment in the phagocytic cells. The liver becomes extremely congested, and the Kupffer cells contain large amounts of malarial pigment. Similar reactions occur in the bone marrow, placenta and other organs. Practically all descriptions of the pathology of malaria are of fatal falciparum infections.

The malignancy of falciparum malaria is peculiar to that species. Eight to eighteen hours after the falciparum parasite has entered the red blood cells these cells become increasingly sticky and tend to adhere to the endothelial lining of blood sinuses and vessels, especially where the circulation may be slow. A cross section of a small venule from a fatal case will usually reveal in each red blood cell around the periphery of the vessel a spot of pigment which is all that remains of the antemortem parasite, whereas of the many red blood cells in the lumen of the vessel only an occasional one will have evidence of a contained parasite. This phenomenon has no relation to "sludging" of the

blood seen in other diseases as well as in malaria, though doubtless it contributes to it.

The "sticky cell" is thus fixed and unable to return to the general circulation. Its contained parasite grows and matures, and at the end of forty-eight hours the cell ruptures, liberating its merozoites, which are capable of infecting new red blood cells. Interference with the function of the vessel may vary from slight to complete occlusion or to actual rupture. The site and extent of this interference with vascular function coupled with an unexplained, seemingly selective localization of parasitized cells in various organs or systems are responsible for the variety of symptoms from falciparum infections. Thus pneumonitis, encephalitis or enteritis may be manifest when the bulk of the infection is in the lungs, brain or intestinal tract.

The release of merozoites where the circulation is slowed facilitates the invasion of near-by red blood cells, so that falciparum parasitemias may be heavy in comparison with those of vivax and quartan, in which the rupture of the schizonts takes place in the active circulation.

Successful treatment stops the growth of parasites in one or all stages in the red blood cells, and immunity appears to increase the speed with which fixed and mobile phagocytic cells take up the naked merozoites and even parasite-containing red blood cells. Changes brought about by vivax and quartan malaria, as well as by the majority of falciparum infections, are completely reversible.

**Clinical Manifestations.** There are no clinical manifestations of malaria which can be said to be peculiar to children.

As with adults, children who acquire malaria fall in two groups: those who have not had previous contact with the disease and have no immunity, and those who have been exposed to repeated infection since birth and by eight to twelve years of age have acquired a high degree of tolerance. The former may quickly become severely ill, whereas the latter may have astonishing parasitemias with relatively few symptoms. In the partially immune child an intercurrent infection sometimes initiates renewed activity of an otherwise quiescent malarial infection.

About ten days after a nonimmune child has been in an infected area he should be observed for such changes in behavior as fretfulness, anorexia, unusual crying or disturbances of sleep. Fever may be absent or increase gradually for one or two days, or the onset may be sudden with temperature

up to 105° to 107° F. with or without a chill. After varying periods the temperature falls to normal or below and sweating occurs.

The paroxysm may be extremely short or may last for two to twelve hours. The child may complain of malaise, headache, nausea, generalized aching, particularly of the back, and occasionally of pain in the abdomen when the spleen has swollen quickly and is tender. In vivax and quartan infections dominated by a single brood the fever is the outstanding and characteristic manifestation, occurring at intervals of forty-eight hours in the former and at seventy-two hours in the latter. If convulsions occur, they abate when the fever falls. Herpetic lesions of the mouth are not uncommon.

In falciparum infections the fever is less characteristic and may even be more or less continuous; the fever may be overshadowed by severe manifestations related to such systems as the cerebral, pulmonary or intestinal ones. Severe nausea and vomiting, jaundice, diarrhea, bronchitis and pneumonitis, delirium, convulsions and coma are common. The red blood cell count and hemoglobin level may decrease rapidly.

The spleen is more commonly enlarged in vivax than in falciparum infections, but the liver is likely to be palpable or tender in both. The behavior of a particular strain of any species of malaria can be deduced only from observation of a large number of patients, since the variations are so great.

Whatever the signs and symptoms, if they disappear with the parasitemia in response to therapy, it may be assumed that they were caused by the malarial infection.

**Blackwater fever.** The dreaded blackwater fever is now seen only rarely. The essential lesion is an intravascular hemolysis of varying degree. It is observed only following attacks of falciparum malaria. Therapy with quinine has been thought to be a causative factor; the disappearance of it in areas where Atabrine has replaced quinine in therapy strongly suggests a causal relationship.

If falciparum parasites are present in the blood during an attack, the child may be treated with amodiaquine, chloroquine or quinacrine; otherwise treatment of the malarial infection is postponed until the hemoglobinuria has abated.

**Diagnosis.** The diagnosis of malaria depends upon identification of parasites in the blood. In the blood smear stained for a differential count, the parasites within the red cells have a red chromatin and bluish cyto-

plasm, but *only* if the nuclei of leukocytes have been stained so that they have a rich blue-violet color. The parasites need never be confused with platelets, which have different densities of the same color.

A thick blood film is most suitable for identification of the parasite. Specific medication should be withheld until parasites are demonstrated; if necessary, examinations should be made morning and evening for three successive days. Thick films are made by spreading blood on a clean, grease-free slide so that, when tilted at a right angle, the blood does not quickly form a drop at the lower border, but spreads slowly to the low point. The slide is then placed flat and permitted to dry without heating. The dry film is dipped in methylene blue phosphate solution for one second only. After washing gently in distilled water until the excess blue is removed, it is placed *face downward* on a curved staining plate, and a freshly prepared solution of buffer water, containing 1 drop of Giemsa stain per milliliter, is run under the slide and allowed to act for six to eight minutes. The slide is again dipped in distilled water, drained and dried with heat. The slides are examined under the oil immersion lens with blue-white light and with an eyepiece of 6 to 8 magnification.\*

**Treatment.** Treatment should not be undertaken until the diagnosis has been established. Owing to the importance of the falciparum infection, it is essential to determine whether this species is present; otherwise species identification is not important.

The adequacy of any drug is based on its ability to control the immediate attack and to eliminate the falciparum infection. During World War II quinacrine was proved to be the first drug capable of accomplishing both. It is not practical to attempt to eradicate all vivax infections at the time of the primary attack, especially if there is the potentiality of reinfection. The fourteen-day treatment should be reserved for patients with vivax infections who have had at least one relapse.

\* Methylene blue phosphate solution is prepared by dissolving 1 gm. of the following mixture in 300 cc. of distilled water and filtering (suitably covered, it may be used for many examinations): Medicinal methylene blue, 1 part; anhydrous disodium phosphate, 3 parts; potassium dihydrogen phosphate, 1 part. Buffer water can be made by dissolving 1 gm. of the same phosphate salts in 1 liter of distilled water in proportion of 6 gm. of disodium acid phosphate (anhydrous) to 5 gm. of potassium dihydrogen phosphate.

If good Giemsa stain is not available, 0.75 gm. of Wright's stain powder is thoroughly shaken several times daily for two days with 65 cc. of pure methyl alcohol and 35 cc. of pure glycerin and ten glass beads. Any glass dish with a depression of 4 mm., as the bottom of a mason jar, may replace the curved staining plate.

Gametocytes of vivax and quartan malaria disappear simultaneously with the asexual forms after treatment with the usual drugs. If the falciparum infection is treated early enough and adequately, gametocytes may never appear. On the other hand, falciparum gametocytes may not appear until after the asexual forms have been absent for some days and may then persist for two to three weeks. No treatment is required unless Anopheles mosquitoes are prevalent, when it may be advisable to follow the regular treatment with a gametocidal drug, owing to the potential danger of the patient to the community.

Ice caps and tepid sponging are indicated when the temperature is over 104° F. The fluid and electrolyte balance should be maintained. Water, fruit juices and other fluids should be offered in small amounts at frequent intervals. Salt tablets may be used if sweating is excessive. No purgation should be given, and the child should be allowed considerable latitude in the selection of his diet. Some form of vitamin B<sub>1</sub> may be given, and, when the acute phase is passed, ferrous sulfate may be prescribed.

Children with severe falciparum infections require much more consideration. When markedly dehydrated with or without shock, they should receive intravenous fluids, including blood. The child should be hydrated, out of shock and urinating as an evidence of restored renal function before antimalarial drugs are given. Injections of Atabrine to markedly dehydrated or even to severely malnourished children may be attended by serious consequences. Malnourished children should receive relatively small doses of antimalarial drugs and then only after initial hydration.

Parenteral administration of drugs may be indicated for children who are vomiting persistently, who are in coma or who cannot be induced to swallow. Only drugs especially prepared for parenteral administration should be used, except in grave emergencies. If quinine is the only drug available, 0.5 gm. may be given intramuscularly every four hours. When coma or convulsions are present, quinacrine hydrochloride as a sterile powder freshly dissolved in 3 to 10 cc. of distilled water, or 3 to 5 cc. of chloroquine dihydrochloride (50 mg. per cubic centimeter) may be given. The doses stated are average ones for a child three years of age. Such intravenous injections should not be given faster than 1 cc. per minute.

**Suppressive medication.** Suppressive medi-

Table 80. Malarial Drugs\*

Key	Drug (U.S.P.)	Synonyms	Tablet Size (Mg.)	Length of Treatment in Days	Total Number of Tablets	How Administered
a	Amodiaquine	Camoquin	200	1	3	Single or divided doses
b	Chloroquine	Aralen	250	3	10	† at time of diagnosis; 2 six hours later; 2 daily for 2 days
		Resorchin	250	3	10	
		Nivaquine	200	3	10	
c	Quinacrine	Atabrine	100	7	24	2 two hours apart on diagnosis;
		Mepacrine	100	7	24	3 daily for 6 days
		Metoquine	100	7	24	
d	Chlorguanide	Paludrine	100	7	21	3 daily for 7 days, plus a, b or c
		Proguanil	100	7	21	for 2 days
		Guanatol	100	7	21	
e	Primaquine	Similar to	15	14	14	1 daily after a or b for vivax
		Pamaquin				
		Plasmochin				
		Pentaquin		1	3	Single dose after a or b for falciparum gametocytes

\* The doses are for nonimmune adults weighing approximately 70 kg. Members of races of less stature and especially those who have been exposed to malaria from birth are adequately treated with two thirds of the doses listed. Outpatients may safely be given the daily dose of the drug as a single administration. Children 12 years of age are treated as adults. For those under 12 years the doses may be modified as follows:

0 to 1 year	$-\frac{1}{4}$ adult dose	Doses to be adjusted to the nearest $\frac{1}{4}$ -tablet.
1 to 3 years	$-\frac{1}{3}$ adult dose	
3 to 6 years	$-\frac{1}{2}$ adult dose	
6 to 12 years	$-\frac{3}{4}$ adult dose	

cation is not recommended for children, since in case of failure the parasites may not be detectable microscopically and a prompt diagnosis is impossible.

In endemic areas infants and preschool children should be protected by screens or nets during the hours of mosquito activity. When ill, irrespective of symptoms, every child from a suspect area should have his blood examined on three successive days.

When medical facilities are lacking, it may be desirable to give a drug for suppressive or prophylactic purposes. Such therapy should never be undertaken casually, and rigid adherence to periodic administration is absolutely essential. It should be continued for six to eight weeks after exposure has ended. In localities of great risk larger doses and more frequent administrations may be indicated. After discontinuance of the drug any mild disorder appearing within the next three months should be suspected as being malaria hitherto masked by the suppressive therapy.

The usual suppressive doses for adults are as follows: amodiaquine, 2 tablets every two weeks; chloroquine, 2 tablets weekly; quinacrine, 1 tablet daily; chlorguanide, 1 tablet (100 mg.) daily, or 1 tablet (250 mg.) weekly or twice weekly.

## KALA-AZAR IN CHILDREN

Three different clinical entities, kala-azar (visceral leishmaniasis), oriental sore (cutaneous leishmaniasis) and espundia (nasal leishmaniasis), are associated with what morphologically appears to be the same organism. Leishmania, a protozoal parasite, which in the human body is a small ovoid or roundish organism measuring 2 to 4 microns in diameter, multiplies in the reticuloendothelial cells of the host. In the sand fly vectors and in cultures the Leishmania assume an elongated, motile, flagellated form.

There is some evidence that the Leishmania responsible for the three above-mentioned clinical conditions are not identical, because dogs which have recovered from oriental sore acquire immunity to the sore, but are not immune to kala-azar. This assumption is further supported by the distinctly different geographic distribution of the three diseases.

**Epidemiology.** Kala-azar is endemic in some parts of the eastern region of India (Assam, Bengal and Madras) and in areas of Africa and China. It has also been reported from some areas of South America (Paraguay, Argentina and Brazil). In certain of the Mediterranean countries and islands kala-azar occurs mainly in infants and is

termed "infantile kala-azar." The causative protozoan, however, is the same *Leishmania donovani* responsible for the Indian, African and American cases. There is no satisfactory explanation for this predilection for infants in the Mediterranean area.

The incidence of kala-azar is declining in the endemic areas. The disease is transmitted by the sand fly, which breeds in cracks and rubble, flies low and only for short distances. Multiple infections in the same household are common. Sand fly control is not difficult to achieve with residual insecticides and other measures; early diagnosis and specific treatment of the human host have also contributed to the decline in incidence. Dogs have been incriminated as animal reservoirs in the Mediterranean area, but they do not seem to be important reservoirs for human infection in other parts of the world.

**Clinical Manifestations.** Fever occurs for prolonged periods, sometimes with afebrile intervals. In the chronic form common in adults and older children, low grade remittent or intermittent fever, rarely over 102° F., is more or less persistent, often with two remissions in the twenty-four hour period. The spleen is usually enlarged within a fortnight after the onset, whereas the liver does not become appreciably larger for some months. Some lymphadenitis, especially cervical, is often present, but is less common in the Indian cases. In the well established disease, splenomegaly, emaciation and anemia produce a typical appearance. In many long-standing cases the skin acquires a strange, earthy gray pigmentation, especially on the feet, hands and abdomen. Hence the name, kala-azar, which, translated from the Indian dialect, means "black sickness." The hair is likely to become sparse and brittle. A peculiar feature in adults and older children is that in spite of the systemic infection the appetite remains good, the tongue is clean, and the patient is often unaware that he has fever. Leukopenia with a relative increase of monocytes and lymphocytes is characteristic. Anemia is often present, but is rarely severe. Purpura, gingivitis and stomatitis are common. Leukopenia, with a relative lymphocytosis, thrombocytopenia and anemia are common and are probably due to displacement of the hemopoietic elements of the bone marrow by parasitized reticuloendothelial cells. Cancrum oris may occur in neglected cases, though most cases of it in children in India are unassociated with kala-azar. Progressive alteration of the plasma proteins

occurs early; the globulin is increased considerably, and the albumin is decreased.

In children the onset is often abrupt with typhoid-like fever and toxemia. Hence they are more apt to receive medical attention early. If untreated, they are more liable than adults to intercurrent infections, such as bronchopneumonia or dysentery, which may prove fatal. For these reasons young children do not reach the stage of gross splenomegaly as often as adults do. Kala-azar in older children in the Mediterranean area runs a subacute course unless terminated by bronchopneumonia or cancrum oris.

The onset in *infantile kala-azar* is acute with high fever and vomiting. Agranulocytosis, which is common, is responsible for the tendency to secondary infections and cancrum oris. Untreated infantile kala-azar is invariably fatal; sudden death may be due to hyperpyrexia, intense dyspnea or hemorrhage. Light-skinned children show pallor rapidly with slight generalized edema resembling that of subacute nephritis. The lymph nodes are usually enlarged.

**Diagnosis.** The diagnosis is established by finding the protozoan (1) in a smear of the peripheral blood, which is rather unusual, (2) in a blood culture on N.N.N medium, (3) in smears or cultures from aspirated bone marrow, and (4) in aspirated material from the liver or spleen. Splenic puncture gives the highest percentage of positive results, but must not be lightly undertaken on account of the risk of fatal hemorrhage, especially when there is anemia and a bleeding tendency. The "formol-gel" test, performed by adding 1 drop of 30 per cent formalin to 1.0 ml. of clear serum of the patient and observing for jellification with opacity, is useful in chronic and subacute cases, but is often negative in the early stages of the acute forms in children. Other presumptive evidence includes leukopenia with decrease of the granular elements, the characteristic fever with double daily remissions when present, and splenomegaly. The early stage may be confused with malaria and typhoid fever, and prolonged or recurring fever may resemble tuberculosis, brucellosis and amebic abscess of the liver. The chronic stage may be confused with Banti's syndrome or with Indian childhood cirrhosis.

**Treatment.** The susceptibility of kala-azar to specific drug therapy appears to vary considerably in different parts of the world. The disease in India is most easily cured by pentavalent antimonials; only an occasional

antimony-resistant case is encountered which requires one of the aromatic diamidine drugs such as pentamidine or stilbamidine, drugs which may be toxic. Visceral leishmaniasis of the Sudan is highly resistant to therapy. The Chinese and Mediterranean forms are

intermediate in their response to therapy. Besides specific treatment, it is important to combat the malnutrition present in these children. Strict oral hygiene is essential to prevent stomatitis and cancrum oris.

S. T. ACHAR

## INTESTINAL PROTOZOA

Unlike most of the worm infections, the severity of disease produced by protozoa is not necessarily proportional to the size of the inoculum. Though protozoa are capable of developing colonies of limitless size, the ultimate population is limited by the area of suitable habitat, immunity and perhaps by other extrinsic factors. Once the colony is established, its reproductive potential is in part used for production of transfer-stages which infect other hosts.

The life cycle of an intestinal protozoan colony typically begins with a single cell, a *trophozoite* (vegetative stage), with one or more nuclei and with specialized structures for locomotion. The trophozoite grows and reproduces by binary fission (*Isospora* excepted). The vegetative functions of some of the trophozoites are interrupted; an enveloping membrane is secreted by the organism and, thus immobilized, is eliminated in the feces. In this stage it is referred to as a *cyst* and is not to be confused with the eggs of higher animals or spores of other organisms. The protozoan cyst is fairly resistant to external conditions, but it rarely reaches a new host in a viable state except in relatively cool, moist media. When the cyst is ingested and reaches its normal habitat in the intestine, the membrane ruptures, and the organism resumes its vegetative functions. By a succession of generations a new colony is formed and the cycle is repeated.

The cyst is passive in its transfer from host to host; thus cysts from the feces of man may be ingested by other animals, and cysts eliminated from other animals may be ingested by man. It was thought that the cysts or the escaping trophozoites were either destroyed in the "abnormal" host or passed through the intestine unchanged and that each host had its individual species. It is now recognized that some intestinal protozoa inhabit a variety of hosts.

Of the ten species of protozoa commonly found in the human intestine, five are ame-

bae (*Entamoeba histolytica*, *Entamoeba coli*, *Endolimax nana*, *Iodamoeba bütschlii*, *Dientamoeba fragilis*), three are flagellates (*Giardia lamblia*, *Chilomastix mesnili*, *Trichomonas hominis*), one is a ciliate (*Balantidium coli*) and one a sporozoon (*Isospora* species). Only two, *Entamoeba histolytica* and *Balantidium coli*, produce serious disease in man, although *Dientamoeba fragilis* and *Giardia lamblia* are frequently classified as pathogens. *Isospora* infection rarely occurs in man. It usually produces only mild symptoms and tends to be self-terminating.

### AMEBIASIS

**Etiology.** Amebiasis is usually regarded as synonymous with *Entamoeba histolytica* infection. *Dientamoeba fragilis* and *Iodamoeba bütschlii* have infrequently been considered pathogens, but neither produces a distinct disease. If either is suspected of producing symptoms, the disease may be treated as infection with *E. histolytica*.

*Entamoeba histolytica* inhabits the colon. It is frequently found in symptomless carriers and is thought by some to be a harmless commensal in the majority of instances. It is potentially a pathogen, however, capable of deep invasion of the bowel wall and of being transported to other organs, especially the liver, where it causes serious damage.

**Epidemiology.** Amebiasis is found in all parts of the world, especially in the tropics, but, like other filth-borne diseases, its distribution and prevalence correlate more closely with standards of personal hygiene and sanitation than with climate. Infection rates may approach 100 per cent in densely populated unsanitary areas and may be extremely low in well sanitated groups. Faust (1953) estimated that the incidence of amebiasis in the general population of the United States may be about 10 per cent; 5 per cent is regarded as a safe estimate. In the United States amebiasis is probably most prev-

alent in the South Central States. In the Charity Hospital at New Orleans routine examinations during the years 1945–56 recorded *E. histolytica* in 3 to 4 per cent of stools from children one to eleven years of age and in 3 to 5 per cent from adults. Possibly because amebiasis is more difficult to diagnose in children than in adults, surveys usually show a higher incidence in the latter. Infrequently the disease appears in epidemic form as in Chicago in 1933, when there were 1400 cases and 100 deaths. The mortality rate in the United States is about 0.1 per 100,000 population.

Infective cysts passed in stools vary from too few to be detected by ordinary means to many millions per day. Stools from ten consecutive patients averaged 241 cysts per milligram of feces. A housefly or cockroach may ingest much more than a milligram of feces, the amebic cysts passing through its intestine unharmed.

Cysts are killed immediately by desiccation and by temperatures above 55° C., but may survive for months in water at temperatures below 20° C. In feces at room temperature they die rapidly after one or two days. They are killed by all commonly used disinfectants, but not by ordinary chlorination of water. Five parts per million of chlorine residual for thirty minutes, however, renders water safe. It has not been shown that contaminated soil is important in the spread of amebiasis through the medium of uncooked vegetables. However, since cysts may survive in moist soil, amebiasis may be contracted by children from dooryard soil. There are no important animal reservoirs of amebic infection, although monkeys, apes and dogs may harbor natural infections, and other animals are readily infected in the laboratory. Amebic infection in dogs is relatively common, presumably owing to their tendency to eat human feces, but they rarely pass cysts in their stools and therefore are not an important source of human infection.

Infection is passed from person to person by means of relatively nonresistant but extremely abundant cysts in feces which, in diverse but mostly unproved ways, contaminate food and water.

**Pathology.** Some strains of *E. histolytica* are more pathogenic than others, and some which fail to produce symptoms in one person may readily produce disease in another. Infection may exist without evidence of disease, other than an abundance of cysts in the stools, and later develop into frank dysen-

tery. Conversely, dysentery may be followed by a carrier state without evidence of disease.

Although massive colonization over its unbroken surface may deleteriously affect the mucosa, the only known means by which amebae produce disease is by tissue destruction in the colon or in other organs secondarily colonized by way of the blood stream. The colon is most frequently invaded at the cecal and sigmoidorectal levels, but the ascending colon, the hepatic and splenic flexures and the appendix are also frequently affected. Involvement varies greatly in area and in depth, the extreme being the full length of the organ and all layers even to, or through, the serosa. Generally, the muscular layers are resistant to invasion. Thus the typical lesion, which tends to be microscopic, develops vertically and secondarily extends laterally, simulating the shape of a flask as the more resistant layers are encountered. Bacteria may be absent from newer lesions, and inflammatory cells may be scant or absent. Older lesions, however, complicated by secondary bacterial invasion, show various degrees of inflammation and suppuration. Microscopically, there is nothing diagnostic in the lesion of the colon except the presence of *E. histolytica* trophozoites.

The hepatic lesion is more characteristic. Trophozoites diffusely distributed through the liver parenchyma produce multiple microscopic areas of necrosis which may coalesce to form a macroscopic lesion, the amebic liver abscess. It usually contains a characteristic pasty brownish material. Occasionally this material is mixed with purulent exudate, and the demonstration of amebae, essential for positive diagnosis, is more difficult.

**Clinical Manifestations.** The 'signs and symptoms of intestinal amebiasis are largely those of nonspecific regional ulcerative colitis. Varying from mild irritation to extensive destruction of the bowel wall, from involvement of one or more local areas to that of the entire organ and from transient minor clinical disturbances to severe chronic disease, the manifestations of amebic infection are so diverse that intestinal amebiasis can never be ruled in or out without the aid of a microscope. Any abnormal bowel activity, unusual stools, abdominal complaints or physical findings suggestive of colonic disease should be an indication for microscopic examination of stools for amebae.

In severe amebic diarrhea, in contrast to bacillary dysentery in that in the former the

onset is less likely to be sudden, fever and leukocytosis are slight or lacking, and the stools lack the odor and appearance of containing pus; i.e., the mucus is clear instead of being whitish or yellowish, and the odor is reminiscent of autolytic rather than suppurative processes. In this latter respect, the diarrheas caused by *E. histolytica* and by whipworm (*Trichocephalus trichiurus*) infections are identical.

Amebic abscess of the liver is uncommon in children. The manifestations are the same as in adults, except possibly more pronounced. Chills, fever, leukocytosis and right upper quadrant tenderness or pain, especially if accompanied by physical signs or roentgenographic evidence of a bulging mass, suggest the possibility of a liver abscess. The demonstration of colonic amebiasis would be supportive evidence, but other causes should be considered. In regions where *Ascaris lumbricoides* is endemic, abscess formation around adult worms in the liver, or enlargement and tenderness of the liver resulting from migrating larvae, is much more frequent in children than hepatic amebiasis.

**Diagnosis.** The diagnosis of parasitic infections by stool examination presents two distinct problems: the detection of some stage of the organism and its identification. The following suggestions may be helpful.

Since all stages of amebae in all types of feces or other material retain their normal appearance longer at room temperature than at body temperature and even longer under refrigeration (but not frozen), stools should be refrigerated promptly if examination is to be delayed more than one hour. Even trophozoites may occasionally remain identifiable for several days.

Abnormal elements in stools, such as mineral oil, fats, bismuth, kaolin, barium, certain foods such as bananas and milk and excessive amounts of undigestible pulpy fruits and vegetables, diminish the chances of finding amebae in the stools.

The advantage in the specimen obtained by purgation, saline enema or proctoscopy is its delivery fresh and on convenient schedule. If watery, it may contain more amebae, but they perish more quickly than in the usual stool. Of twenty-six infections studied by Hood, three were detected by proctoscopic examination, five by stool examination and the remainder by both methods.

Reliability of negative findings is increased proportionally with the number of

stools examined, provided the stools vary in kind as well as in time. Time should not be taken to examine unsatisfactory specimens. It is important that laboratory reports include a description or an evaluation of the material examined.

A large specimen permits selection of favorable samples, but overemphasis of this factor may delay diagnosis, especially of waning dysentery. An ideal microscopic preparation contains only 1 to 2 mg. of feces, and most concentration methods require less than 1 gm. A fleck of feces obtained from the rectum on the gloved finger or from a saline enema may be sufficient.

If reliable diagnostic service is not locally available, fecal specimens and material aspirated from the colon or from liver abscesses may be satisfactorily preserved and mailed to distant laboratories by using one of the procedures described below. The material *must* be freshly collected, diluted with 5 parts or more of the fixative-preservative and must be well comminuted.

**Methods for preservation of stools.** (1) Ritchie (1948) found that 1 part of full-strength commercial formaldehyde solution diluted with 9 parts of water is a good general fixative-preservative. One cubic centimeter of feces in 10 cc. of fixative is an adequate specimen. On reaching the laboratory the material is strained, mixed with ether and concentrated by centrifugal sedimentation. This is not as satisfactory as other techniques for dysenteric stools and aspirates, but it is probably the choice for mushy or formed stools.

2. Brooke and Goldman (1949) described a fixative-preservative prepared by adding 5 gm. of powdered polyvinyl alcohol ("Elvanol" 90-25, E. I. du Pont de Nemours) to 1.5 cc. of glycerin, 5 cc. of glacial acetic acid and 93.5 cc. of Schaudinn's solution (2 parts of saturated aqueous solution of mercuric chloride to 1 part of 95 per cent ethyl alcohol), heated to about 75° C. and stirred until clear. One cubic centimeter of feces in 5 cc. of fixative is an adequate specimen. On its reaching the laboratory, slides are prepared and stained with iron-hematoxylin.

3. Saper, Lawless and Strome (1951) use a fixative-preservative consisting of two solutions, stored separately and mixed immediately before use. Solution I is 40 parts of tincture of Merthiolate (Lilly), 5 parts of formaldehyde (U.S.P.) and 1 part of glycerin. Solution II is freshly prepared Lugol's solution (5 per cent iodine in 10 per cent aqueous potassium iodide solution). For use, combine 15 parts of solution I with 1 part of solution II. One cubic centimeter of feces in 8 to 10 cc. of preservative is an adequate specimen. Wet smears of the mixed specimen or the sediment are examined microscopically without further staining.

Cultures of fecal or aspirated material are generally not practical. Although mul-

tiplication of amebae is often obtained in cultures, experienced workers have little confidence in negative findings.

Complement fixation is not a dependable test.

**Prognosis.** Once a diagnosis of colonic amebiasis has been made, early eradication of the parasite is a definite probability. In the absence of reinfection, chronic refractory infections requiring long, varied and multiple treatments are exceptional. With proper corrective and supportive measures even severe dysentery usually can be controlled within a few days and cured within two or three weeks. Except for amebic abscess of the brain, which is rare even in adults, the prognosis is also good in early diagnosed extraintestinal infections.

**Prevention.** Contaminated water and food are probably the only important sources of amebic infection in adults. In children the transfer of infection occasionally may be more direct, and contaminated dooryard soil is a possible though unproved source of infection. Water and certain foods may be made safe by boiling or scalding. When boiling of water is impractical, hyperchlorination or halogenation with iodine by means of commercially available preparations is possible. Thoroughly dried foods may be regarded as safe. Rooty vegetables and fruits can be washed and peeled, and leafy vegetables can be safely eaten after thorough washing and immersion in full strength vinegar (5 per cent acetic acid) for fifteen to twenty minutes at room temperatures. The prophylactic use of glycobarsol or Diodoquin in doses of one sixth to one third of the therapeutic ones has been recommended. Sterilization of dooryard soil is not feasible.

**Treatment.** For children with acute dysentery or severe diarrhea due to *E. histolytica*, Milibis (glycobarsol) is a relatively safe, inexpensive and effective drug. Tetracycline or emetine may be given for speedier control of symptoms, but, because of cost, toxicity, and cure rates, they usually are not used as curative drugs. Milibis is administered orally in 250- or 500-mg. tablets three times daily with meals for eight days, the single dose being 500 mg. for adults and for children over six years of age and 250 mg. for younger children. Though generally nontoxic, treatment should be interrupted if such untoward symptoms as dizziness, severe headache, abdominal cramps or neuritis are noted. Tetracycline may be given alone or simul-

taneously with Milibis. The dosage for children is 5 to 10 mg. per pound of body weight three times daily for two to four days, or until acute symptoms subside. Emetine similarly administered may be more effective and is less expensive than the tetracyclines (see below for dosage). Although somewhat less effective than Milibis, some of the older drugs such as Diodoquin, chiniofon (Anayodin, Yatren) and carbarsone are often satisfactory.

Three or four stool examinations should be made at weekly intervals after discontinuance of treatment. If symptoms persist despite negative findings on satisfactory fecal specimens, efforts should be made to discover causes other than amebic infection. Because amebae may appear in the stools within a few days after reinfection, positive findings on treated outpatients should not be interpreted as necessarily indicating failure of treatment.

Hepatic amebiasis, apparent or presumed to be highly probable, in the presence of demonstrated colonic infection, usually is treated with chloroquine phosphate. The drug is administered orally in 250-mg. tablets and may be given simultaneously with the treatment for colonic infection. The dose for children under six years of age is 250 mg. twice daily for two days followed by 125 mg. twice daily for twelve additional days; for older children and adults the dose is doubled. When chloroquine fails in the treatment of amebic liver abscess, emetine is used. It is obtainable in 1-cc. ampules containing 65 mg. of emetine hydrochloride and is injected subcutaneously in doses of 0.5 mg. per pound of body weight per day for not more than ten days, and never in excess of 6.5 mg. per day. Emetine may produce neuritis or irreversible myocarditis, so that its use should not be repeated in less than one month.

## GIARDIASIS

*Giardia lamblia* is most frequently found in the tropics and subtropics, its distribution seeming to vary with economic, hygienic and sanitary conditions. Faust and Headlee observed a high incidence in white children in New Orleans, 8.6 per cent at one year of age, 19.3 per cent in the seventh year and 13.8 per cent in the tenth year. Though the parasite may be transmitted by food and water and by houseflies, it is most commonly carried directly from person to person.

The flagellate usually lives in the duodenum and upper jejunum, where it may persist for years, or disappear spontaneously, especially in older children and adults. Trophozoites die within a few hours outside the body, but cysts may remain viable for as long as sixty days.

The pathogenicity of *Giardia lamblia* has not been satisfactorily demonstrated. It has frequently been demonstrated in stools of children with a variety of complaints referable to the abdomen in general and to the intestinal tract in particular. Proof of its connection with the clinical disturbances, however, is still lacking. Observations in this country do not support the contention that the organism is responsible for significant disturbances. The experience of Véghelyi in Hungary has been the most convincing in support of the pathogenicity of *Giardia*. He reported a high incidence of abdominal and intestinal symptoms among children infected with *Giardia*. The clinical disturbances were mainly abdominal pain and diarrhea, but a significant number also had manifestations of the celiac syndrome. The disappearance of the symptoms after eradication of the parasite by treatment with acetarsone he regarded as proof that *Giardia* was the etiologic agent.

Fortunately the infection is easily eradicated by drugs that are neither expensive nor very toxic. Quinacrine dihydrochloride (Atabrine) administered orally in 0.1-gm. tablets for five days in the following dosage rarely if ever fails to result in complete removal of *Giardia*: for adults and children over eight years of age, 1 tablet three times daily; for children four to eight years,  $\frac{1}{2}$  tablet on the same schedule; and for younger children,  $\frac{1}{2}$  tablet twice daily.

## BALANTIDIASIS

*Balantidium coli* is a parasite which, like *E. histolytica*, colonizes the colon. More often than in man it is found in monkeys and pigs, both of which tolerate the infection without apparent damage. Although *Balantidium coli* is the only ciliate protozoon known to parasitize the human colon, numerous morphologically similar organisms are frequent in stools as contaminants and may lead to errors in diagnosis. Diagnosis is established by the presence of either the more or less uniformly ciliated, large, rapidly motile trophozoites or the large spherical cysts.

Balantidiasis is rare in the United States,

but is relatively common in Puerto Rico, Mexico and various parts of South America. Most of the human infections apparently are derived from pigs. Under crowded or unsanitary conditions, especially in institutions, person-to-person transfer of infective cysts commonly occurs. As a rule, however, cysts are formed only sparingly or not at all in the human intestine.

Typically, the infection is of short duration, producing in children a disease similar to amebic dysentery. The pathologic changes are likewise similar, both in distribution and character. The chief difference is the greater tendency of balantidiasis toward spontaneous cure. This factor has led to variable interpretations of the curative value of tested drugs. Carbarsone, regarded as the drug of choice, frequently fails to effect cures. Satisfactory results appear to be obtained with tetracycline given orally in doses of 8 to 10 mg. per pound of body weight three times daily for ten days, the total dose not to exceed 2 gm.

### TOXOPLASMOSIS

The parasite *Toxoplasma gondii* was first described by Nicolle and Manceau and by Splendore in North Africa and in Brazil, re-

spectively, in 1908. In 1939 Wolf, Cowen and Paige isolated the organism from infants who had died of congenital encephalomyelitis, demonstrating for the first time that *Toxoplasma* could produce human illness. It soon became apparent that the disease could be acquired in utero, termed the congenital form, or at any time postnatally, the acquired form. Acquired toxoplasmosis was encountered either as an acute encephalitis or as a rickettsial-like illness with pneumonitis and a maculopapular rash. Sabin devised a rabbit neutralization test with which specific serologic studies could be performed, and also pointed out that congenital toxoplasmosis frequently produced chorioretinitis, cerebral calcification, psychomotor retardation, hydrocephaly or microcephaly and convulsions. With the development of the dye, complement fixation and skin tests in 1948, practical specific methods became available for intensive study of the disease. Among the unanswered questions are those concerned with the sources and the pathogenesis of human infections.

**Etiology.** *Toxoplasma gondii* is considered to be a protozoon, but its precise classification remains in some doubt. It is a delicate, oval or crescent-like organism measuring 2 to 4 by 4 to 7 microns. It divides by binary fission and is best stained with either Giemsa or Wright stain. *Toxoplasma* is unique in that it may invade any tissue (with the possible exception of the erythrocyte) of mammals and birds; multiplication has been noted only in the presence of living cells. *Toxoplasma* does not withstand freezing, except under special conditions, and sediments readily during ordinary centrifugation. There is only one *Toxoplasma* species, and all strains isolated to date have been serologically homogeneous.

**Epidemiology.** The prevalence of *Toxoplasma* antibodies among normal populations varies considerably in different parts of the world. Significant titers of dye test antibodies may be present in 50 per cent or more of the inhabitants of some localities, so that the interpretation of serologic findings in older children and adults in such areas is almost impossible unless real changes in titer are demonstrated in serial samples. Among various animal species surveyed by the author approximately 30 per cent of swine and cats had significant amounts of antibody, and half or more of goats and dogs were positive. This relatively high rate of specific antibody titers among animals makes it difficult to

determine the relationship of a particular animal to a specific human infection.

Any of the clinical manifestations of congenital toxoplasmosis may be produced by other diseases. Hence any single finding or combination of findings is not sufficient in itself to establish the diagnosis. For example, in our experience, of children suffering from chorioretinitis, only 41 per cent of those under one year of age, 49 per cent of those between one and four years, and 62 per cent of those between five and nine years were found to have satisfactory serologic criteria for congenital toxoplasmosis. Thus, in at least half or more of childhood cases of chorioretinitis, congenital toxoplasmosis could not be incriminated. These data, however, may not be applicable in all sectors. A similar tabulation was made among children with cerebral calcifications; approximately half of the children nine years of age or younger were found not to have congenital toxoplasmosis.

**Pathology.** In the congenital form histologic changes are most frequent in the central nervous system, but may be found in almost all tissues, as is the case in the acquired type. The retina and choroid are usually involved in the congenital form, and such lesions have recently been noted in a few cases of acquired toxoplasmosis. Gross or microscopic areas of necrosis may be found in many tissues, especially in the heart, lungs, skeletal muscle, liver and spleen. *Toxoplasma* may be seen as pseudocysts (particularly within muscle) or as individual organisms, often with surprisingly little tissue reaction. Single or multiple areas of calcification, both large and small, may be present in necrotic areas of brain in the congenital form, but have not been found in acquired cases. The lesions of toxoplasmosis are not sufficiently characteristic to permit a specific diagnosis in the absence of other information or of demonstration of parasites. Recently, parasites have been identified in sections of lymph nodes; their presence in nodes has also been confirmed by animal inoculation.

**Clinical Manifestations.** Human toxoplasmosis may occur as a congenital or acquired disease. Although there is no evidence that the congenital disease is ever inapparent, most acquired infections occur in a clinically non-recognizable form, and presumably account for the fetal infections.

**Congenital toxoplasmosis.** The fetus infected with *Toxoplasma* may be stillborn or born prematurely or at term. Illness which

is apparent at birth or does not become evident for several days may manifest itself with malaise, fever, maculopapular rash, icterus, lymphadenopathy, hepatomegaly, splenomegaly, hydrocephaly, microcephaly, microphthalmia and convulsions. The cerebrospinal fluid may be xanthochromic and contain an increased number of cells (sometimes eosinophils) and protein. Cerebral calcifications and chorioretinitis may be present at birth or develop in ensuing weeks. Congenital toxoplasmosis may be diagnosed in this stage by demonstration of parasites in smears from the sediment of cerebrospinal or ventricular fluid. There is a high dye test titer in both mother and infant, but though the maternal complement fixation test is positive, the infant's may or may not be. Active congenital toxoplasmosis may terminate fatally in days or weeks, or the illness may regress, leaving varying degrees of disability such as hydrocephaly or microcephaly, chorioretinitis, psychomotor retardation, ocular palsies or convulsions. The full impact of the infection may not become evident until some weeks or months after apparent recovery. Live parasites were isolated from the brain of a child with a congenital infection who died in his fourth year.

In a large group of cases of congenital toxoplasmosis collected by the author, 31 per cent of the infants were born prematurely, of whom 27 per cent died. Of those born at term, 12 per cent died. In this series chorioretinitis was noted in 99 per cent, cerebral calcification in 63 per cent, psychomotor retardation in 56 per cent and hydrocephaly or microcephaly in about half of the cases. Neither the cerebral calcification (single or multiple) nor the chorioretinitis was sufficiently characteristic to permit an etiologic diagnosis. Chorioretinitis was bilateral in 85 per cent of the cases and almost equally distributed between the left and right eyes in the remainder.

There is suggestive evidence that fetal infection occurs only after the placenta has been formed. All offspring in a multiple pregnancy are infected, although the degree of damage of each may vary.

Toxoplasmosis does not appear to be important as a cause of prematurity, cerebral palsy, blindness or "uncomplicated" mental retardation. The disease apparently occurs only once among the offspring of a given mother.

**Acquired toxoplasmosis.** Acquired toxoplasmosis most frequently is unrecognized

clinically. Parasitemia probably occurs in such infections and presumably is the mechanism by which the fetus becomes infected in the pregnant woman. With the exception of occasional instances of lymphadenopathy, no indication of maternal infection has been noted.

Symptomatic acquired toxoplasmosis may occur at any age and with almost any combination of the following manifestations: malaise, fever, myalgia, maculopapular rash, generalized lymphadenopathy, splenomegaly, encephalitis, pneumonia and myocarditis. The illness may be symptomatic for a few days or for some weeks. The incubation period, source of infection and mortality rate are unknown, but most patients seem to recover spontaneously. If chorioretinitis occurs during the acute, acquired form, it must be rare.

**Laboratory Diagnosis.** The best evidence of infection is the demonstration of parasites in wright- or giemsa-stained impression smears of tissues or in films made from the sediments of centrifuged cerebrospinal or ventricular fluids. Final identification depends upon isolation of the parasites in animals; the laboratory-reared mouse is ideal. The inoculation should be made with suspensions of fresh tissue or body fluids.

The dye test, a sensitive, reliable indicator of *Toxoplasma* antibody in human or animal serums, is performed by incubating mixtures of various dilutions of inactivated serum of the patient with living parasites (mouse peritoneal exudate) which have been suspended in fresh, antibody-negative human serum. The latter serves as a source of a heat-labile serum component (activator) which is necessary for the action of the specific antibody. After incubation at 37° C. for one hour, alkaline (pH 11.0) methylene blue is added to the test mixture, which is then examined under the microscope. If antibody is absent, the parasites are stained blue; if present, their cytoplasm will be unstained. The dilution of serum in which 50 per cent of the parasites are unstained represents the end point (titer) of the specimen. *Toxoplasma* antibody, as determined by the dye test, tends to appear early in the infections and to remain in high titer for some months or years; the titer then diminishes gradually, but some antibody persists for years, if not for life. Titers of 1:1000 to 1:16,000 are usual for at least some months in the serums of mothers and of infants or young children with congenital disease. If the infant's antibodies have been

acquired by passive transfer, there will be a sharp decline in titer by three months of age and almost total disappearance by six months.

The complement fixation test, which has been used less widely than the dye test, offers additional aid. It becomes positive more slowly, so that early in the disease there may be a strongly positive dye test with a negative complement fixation one. Conversely, the complement fixation reaction tends to decrease relatively quickly, so that within months or several years after the illness (or birth) there again may be a negative complement fixation reaction and a positive dye test. An infant born with active disease may have a negative complement fixation test but a positive dye test, despite the mother's serum having high titers by both procedures.

A skin test (antigens from either egg or mouse peritoneal fluid) is available, but of questionable aid in a specific situation, since positive reactors are prevalent in the general population. The time required for the development of skin sensitivity is unknown, but positive reactions have not been encountered in children under four years of age in any survey among the general population.

Two new methods for demonstrating antibodies for *Toxoplasma* have been reported recently. One of these is a hemagglutination test in which sheep erythrocytes treated with tannic acid serve as the vehicle for a soluble *Toxoplasma* antigen. The results seem to parallel those obtained with the dye test, but the usefulness of this test must await further experience.

The second test is somewhat more complex. The antibody content of a serum is measured by its ability to interfere with the fluorescent staining of killed *Toxoplasma* by a fluorescein-labelled antiserum. It has been proposed as a screening procedure before performing the dye test. Its advantages remain to be determined.

**Treatment.** Eyles has observed that the combination of pyrimethamine (Daraprim) and sulfadiazine is superior to either drug alone in the treatment of experimental mouse infections and has suggested a trial of this combination in human infections. A number of patients now have been treated in this way, and although the results are promising, the inability to predict the natural course of the disease makes critical analysis rather difficult. Nevertheless, this combination appears to be the best form of therapy currently available. Sulfadiazine should be administered in usual therapeutic doses with

the pyrimethamine in divided doses on the basis of 1 mg. per kilogram of body weight per day. Treatment should be continued for about two weeks, and leukocyte counts should be repeated frequently, since pyrimethamine, an antifolic agent, as well as the sulfonamide may produce severe leukopenia.

# The Digestive System

## THE ORAL CAVITY

### EXAMINATION

The condition of the oral cavity has considerable influence on the nutritional status and psychologic development of the child. The physician should know what constitutes good oral hygiene and adequate management of oral disturbances. He should develop skill in examination of the oral cavity so that he can perform it with the least possible discomfort to the child. At best it is likely to be the most disturbing part of the physical examination and should be left until last. Examination of the anterior part of the mouth should occasion no discomfort and should be completed before the throat is examined. In the older child, gagging can be avoided if he breathes actively through his mouth during the examination of the throat. Infants, of course, must be held by an attendant, who, standing at the head of the infant, extends the arms beside the head and holds the arms and the head together by cuffing his (the attendant's) hands over the infant's elbows in such a way that his fingers are directed toward the occiput and the thumbs are at the temple area.

Good intraoral lighting is essential; the otoscope or a flashlight with a condensing or "spotlight" lens is satisfactory. The ordinary wooden tongue blade is too big and clumsy for the small mouth of the infant and young child; it may also produce trauma. The straight blade tends to push the base of the tongue back against the postpharyngeal wall, whereas a curved spoon handle or a mouth mirror placed on the base of the tongue enables the physician to pull the tongue down and forward.

### ORAL HYGIENE

**Natural Means.** Oral hygiene is largely a mechanical cleansing process, and can be achieved by natural mastication, provided the diet includes hard, coarse and fibrous foods

which must be chewed thoroughly before they can be swallowed. The action of the tongue, the labial musculature and the saliva aid the cleansing action of such foods.

At six to eight months of age the child can be given some hard food such as zwieback which will assist in the cutting of the teeth. Later, raw apples, oranges and other fruits become splendid tooth cleaners, but cakes and starchy and sticky foods are noncleansing, tend to adhere to the teeth and thus favor food stagnation and decomposition.

**Artificial Means.** Before the teeth are erupted, artificial cleansing of the healthy mouth is superfluous. Because the oral mucosa is thin and easily injured in the infant and young child, brushing of the teeth should not be started before the third year. Until that time the crowns of the teeth may be occasionally cleansed with a cotton-tipped applicator soaked in saline solution or a dilute sodium bicarbonate solution. During the third year the mother should start the brushing of the child's teeth and by the fifth year the child usually assumes the responsibility. Modern man needs to brush his teeth to remove collections of soft and sticky foods; brushing helps to control dental caries and periodontal disorders, but cannot entirely prevent them.

The child should be taken to the dentist at the age of three years and should return every six months. The first visits permit early recognition of decay that can be treated easily and painlessly and also minimize any tendency to fear the dentist.

**Oral Hygiene in the Sick Child.** Oral hygiene is especially important for the sick child. The nurse should free the mouth of its debris by cleansing the oral mucosa and the teeth at least twice daily with gauze placed around her index finger and soaked in a mild antiseptic. This should be followed by rinsing the mouth with iodosaline (1 per cent tincture of iodine in warm saline solu-

tion). No oral care is necessary for the sick infant beyond that of an adequate intake of water.

The convalescent child should be taught

the technique of brushing teeth. Iron or acid preparations in liquid form should be taken through a straw to avoid discoloration or dissolution.

## DISTURBANCES OF THE TEETH

**Life Cycle of the Tooth.** Each tooth undergoes four successive periods of development during its life cycle: growth, calcification, eruption and attrition. All the common developmental aberrations of the teeth may be classified according to the developmental stage affected (Table 81, p. 621). The earlier the tooth is affected, the more severe the result.

### DISTURBANCES IN GROWTH

#### INITIATION OR ABNORMALITIES IN NUMBER OF TEETH

**Deficient Number of Teeth.** *Anodontia* may be complete or partial and results from a lack of initiation or from an arrest in proliferation. Clinical absence of teeth, however, is not sufficient evidence to warrant a diagnosis of anodontia, and roentgenographic examination is essential before failure in eruption can be excluded.

The third molars, the upper lateral incisors and the lower second bicuspid are, from an evolutionary point of view, vestigial organs, and abnormalities or absence of them has no clinical significance. The congenital absence of other teeth, however, is likely to be associated with such congenital dysplasias as cleidocranial dysostoses, arachnodactyly and congenital ectodermal dysplasia.

**Supernumerary Teeth.** An excessive number of teeth usually results from continued budding of the enamel organs of the preceding teeth. Supernumerary deciduous teeth are much less common than supernumerary permanent ones.

#### PROLIFERATION

Proliferative malformations may have a variety of forms and causes.

**Cysts.** Cysts may originate from abnormal proliferation of the oral epithelium or more commonly from proliferation of epithelial rests in the periodontal membrane.

**Ameloblastomas.** These tumors arise from the enamel organ (see p. 1369).

**Odontomas.** When abnormally proliferating cells of the enamel organ undergo partial

or complete differentiation, calcified toothlike masses are formed which are termed odontomas. These may range from small calcific nodules to well formed teeth. They usually do not erupt and are never malignant.

#### HISTODIFFERENTIATION—

##### ABNORMALITIES IN STRUCTURE OF ENAMEL AND DENTIN

**Amelogenesis Imperfecta (Brown Teeth).** When the ameloblasts (enamel-forming cells) fail to differentiate properly, a thin layer of enamel is deposited, and the underlying brown dentin is readily visible. The condition is hereditary.

**Hereditary Opalescent Dentin (Dentinogenesis Imperfecta).** Brown opalescence of the teeth and marked abrasion characterize hereditary opalescent dentin. The roentgenographic appearance is pathognomonic, the pulp chamber being entirely absent and the pulp canals showing progressive decrease in size. The roots are usually shorter than normal. Both the deciduous and permanent teeth are affected. The dentin is abnormal in formation and calcification, and the tubules are reduced in number and are irregular in arrangement. The pulp cavity is completely obliterated by excessive dentin formation. The teeth wear rapidly, and their protection by special restoration is indicated as soon as they appear.

Dentinogenesis imperfecta is hereditary and often accompanies other congenital mesodermal dysplasias, particularly osteogenesis imperfecta. Each may occur separately, but in combination the condition is termed *congenital mesodermal dysplasia*.

**Abnormalities in the Color of Teeth. Intrinsic stains.** The brown teeth characteristic of dentinogenesis imperfecta and amelogenesis imperfecta are described above. A greenish color of the enamel being formed at birth may result from intense neonatal jaundice, and the deciduous teeth may be completely green except for the portions formed postnatally. In congenital porphyria the teeth are often stained pink. Hemorrhage into the pulp after trauma may cause a gray to black discoloration of the crown.

Table 81. A Classification of Aberrations in Tooth Development

CHARACTER OF DISTURBANCE	GROWTH				CALCIFICATION	ERUPTION	ATTRITION
	INITIATION	PROLIFERATION	HISTO-DIFFERENTIATION	MORPHO-DIFFERENTIATION			
DEFICIENT DEVELOPMENT	ABNORMAL NUMBER	ATYPICAL STRUCTURE	ATYPICAL FORMS & SIZES	ABNORMAL AMOUNT	ABNORMAL HARDNESS	ABNORMAL ERUPTION	ABNORMAL WEARING
	Anodontia - partial or complete Congenital absence of lateral incisors, third molars, bicuspids, etc.	Amelogenesis Imperfecta (Ameloblasts) Dentinogenesis Imperfecta (Odontoblasts) Vitamin A Deficiency (Odontogenic Epithelium)	Peg teeth Hutchinson's incisor Mulberry molars Microdontia	Hypoplasias - systemic or local Chronologic enamel hypoplasia Localized enamel pits Dentin hypoplasia (Pulpal inclusions)	Hypocalcification Mottled (chalky) enamel Malacotic enamel Interglobular dentin	Delayed Eruption of teeth single or multiple Submerged denture teeth Submerged teeth (ankylosis) Impacted teeth Malposed teeth	Deficient Wear Restricted lateral excursion
EXCESSIVE DEVELOPMENT	Epithelial Rests	Odontogenic Epithelium	Extra cusps and roots Dens in Dente Macrodonia	Enamel nodules Simple compound and complex odontomes	Sclerotic Dentin resulting from age, injury or caries	Malocclusions Excessive mesial and occlusal drift of teeth Supraocclusion of teeth	Excessive Wear Night grinding (Bruxism)

From Massler and Schour: Atlas of the Mouth. American Dental Association, Chicago.

**Extrinsic stains.** Green stain occurs on the labial surfaces of the anterior teeth near the gingivae in children who lack satisfactory oral care. It is probably caused by chromogenic bacteria which adhere to gingival mucous plaques or to remnants of the enamel epithelium (Nasmyth's membrane) which have not been worn off in the protected gingival areas. This stain is firmly attached to the enamel and can be removed only by the dentist.

Black stains on the teeth may result from ingestion of iron compounds if a drinking tube is not used to prevent contact with the teeth.

#### MORPHODIFFERENTIATION—

##### ABNORMALITIES IN FORM AND SIZE OF TEETH

**Peg Teeth.** Peg teeth are cone-shaped and small in size. They occur frequently in the congenital dysplasias and may be familial. The upper lateral incisors are most commonly affected.

**Macroteeth or Microteeth.** Excessively large or small teeth are usually hereditary.

**Hutchinson's Incisor.** The incisor has a screwdriver appearance as a result of convergence of the mesial and distal sides (see Syphilis, p. 475).

##### ABERRATIONS IN APPPOSITION

**Enamel Hypoplasia (Pitted Enamel).** This is a developmental defect which appears clinically as a pitting or grooving of the enamel surface and occurs in 5 to 10 per cent of the population. It is a permanent record of a systemic disturbance which injured the enamel-forming cells and caused a premature cessation of their activity. Severe systemic upsets such as congenital syphilis and prolonged diarrhea or vomiting in the first year of life may result in enamel hypoplasia. Many children with persistent cerebral disorders have enamel hypoplasia. Most of the enamel hypoplasias are formed during infancy and may be recognized roentgenographically before eruption of the teeth.

Enamel hypoplasia may also be of local origin and confined to a single tooth. An infection at the root of a deciduous molar may injure the subjacent developing crown of its permanent successor and produce a permanent defect in its enamel.

*A knowledge of the time of tooth formation facilitates chronologic assessment of enamel hypoplasia.* All the deciduous teeth start forming in utero, but are not completed

until about two and a half years of age. The first permanent molar begins its formation at birth and is the first permanent tooth to erupt (about six years of age). It is frequently mistaken for a deciduous tooth and thus often inadequately cared for.

The roots of the permanent teeth usually do not complete development until about three years after eruption of the tooth.

#### DISTURBANCES IN CALCIFICATION

**Interglobular Dentin.** Deposition of mineral salts, as in bone, follows closely the deposition of the matrix. Slight disturbances in calcification are evidenced as interglobular dentin, or *chalky enamel*. Such alterations represent relatively mild systemic disturbances and are often the result of subclinical variations in calcium metabolism (see Mottled Enamel).

The calcification of the enamel and dentin is characteristically different during the various developmental periods (Table 82). It is so sensitive to metabolic changes that these tissues reflect the developmental pattern of the child and serve as a graphic record of past systemic disturbances.

**Mottled Enamel (Dental Fluorosis).** In contrast to normal enamel, which is hard, glossy and translucent, mottled enamel is opaque and, in severe cases, chalky and crumbles easily. It is usually caused by ingestion of excessive amounts of fluorides (more than one part per million of water) during the period of calcification of the developing teeth. The fluorides are usually derived from drinking water from artesian wells in endemic areas. In mild cases there are white opaque areas involving up to 50 per cent of the tooth surface. In moderate cases the entire surface is affected, and brown staining occurs secondarily from oral pigments. In severe cases there is extensive mottling and discrete or confluent hypoplastic pitting.

#### THE TEETH IN DIETARY DEFICIENCIES

The importance of nutrition varies with the developmental stage of the tooth and the particular dental structure. Nutrition is of greatest significance in the infant and younger child when most of the teeth are undergoing formation and calcification. As the teeth erupt into the oral cavity, nutritional factors become relatively less important, and finally play no direct role. It is

Table 82. Effects of Developmental Disturbances in the Structure of Teeth

Normal Structure		Enamel Hypoplasia
Prenatal period		
(4½ months to birth).....	Optimal calcification of enamel and dentin	Often associated with congenital cerebral disorders (especially athetosis or spastic diplegia)
Neonatal period.....		
	Microscopic line of arrested growth demarcating prenatal and post-natal tissue; due to physiologic adaptation and trauma incident to birth	Present in children suffering from excessive birth trauma and brain damage due to anoxia, etc. ("spastics" and mentally deficient children)
Infancy period		
(1-10 months).....	Poor calcification of enamel and dentin	Chronic hypoplasia from birth to 11 months most common form of enamel hypoplasia; usually due to disturbances in calcium metabolism Acute hypoplasia at 10-11 months also common; etiology unknown
Childhood period		
(1-5 years).....	Improved calcification of enamel and dentin from 1 to 2½ years; poorer calcification from 2½ to 5 years	Acute hypoplasias seen occasionally; may be associated with acute illnesses

useless to add calcium or vitamins to the diet to treat enamel hypoplasia or caries. By contrast, the growth of the gingivae, the alveolar bone and the other periodontal structures is influenced by nutrition throughout life.

A diet adequate for general health is also adequate for dental health. Special attention, however, should be given to the physical make-up of the food and its local detergent action and to avoidance of excess sugar.

*Vitamin A deficiency* is rarely sufficiently severe to cause enamel hypoplasia, although in experimental animals it produces striking disturbances.

*Vitamin D deficiency* results in disturbed calcification of the growing alveolar bone and the dentin and occasionally is responsible for enamel hypoplasia. A causal connection between deficiencies of vitamin D and/or calcium and the occurrence of caries has not been proved.

*Vitamin C deficiency* is responsible for hemorrhages in the oral mucosa and gingivae. The use of vitamin C for bleeding gums, postoperative hemorrhage and in oral infections cannot be expected to be beneficial, however, except in the presence of a deficiency of vitamin C.

*Deficiencies of the B complex vitamins*, particularly of riboflavin and nicotinic acid, favor the occurrence of specific infections in the oral cavity. The characteristic changes

of the tongue and other oral tissues are discussed on pages 365 to 367.

DISTURBANCES IN THE ERUPTION OF TEETH

The appearance of the tooth in the oral cavity is only one phase of the eruptive process, which continues throughout life, but at a decelerating rate. The time of the eruption of the teeth is a valuable clinical index of the rate of maturation of a child (Tables 83, 84). The lower teeth usually erupt before the corresponding upper ones, and

Table 83. Time of Eruption and Shedding of the Deciduous Teeth\*

<i>Eruption</i>			<i>Shedding</i>	
	Lower	Upper	Lower	Upper
	Age (Months)		Age (Years)

Third molars.....	17-21	17-21

\* From Massler and Schour: Atlas of the Mouth. American Dental Association, Chicago.

teeth usually erupt earlier in girls than in boys. There is also a normal variation according to constitutional type: Thus teeth tend to erupt earlier in slender children than in stocky ones. Disturbances in eruption of permanent teeth are more common than disturbances in their formation and calcification, and are usually caused by premature extraction of deciduous teeth.

PREMATURE ERUPTION

Occasionally one or two deciduous teeth in the lower central incisor area are erupted at birth or soon after (natal teeth). These may be normal or supernumerary teeth. The latter are exfoliated before the normal teeth erupt and are characterized by looseness, lack of root formation and defective structure. They should be removed if they interfere with nursing or if there is danger of aspiration.

DELAYED ERUPTION

Within normal limits the first deciduous tooth may not appear until the age of one

year. Further delay in eruption suggests a systemic disturbance of nutritional or endocrine origin. Cretinism, rickets, mongolism and congenital syphilis are among the more likely causes. The possibility of total or partial anodontia must be ruled out by roentgenographic examination.

DIFFICULT ERUPTION OR TEETHING  
(DENTITIO DIFFICILIS)

In the early part of this century a great number of disorders (fever, convulsions, diarrhea, croup) were often mistakenly attributed to dentitional difficulties. Eruption is a physiologic process and is not related to the many temporary systemic disturbances that frequently occur during infancy and childhood. There is little basis for the view that eruption of a tooth causes fever. There are instances when the process of teething appears to irritate the child and may be associated with fretfulness, disturbed sleep, salivation and a tendency to put the hand constantly into the mouth. Reassurance to the parents and elimination of other diagnostic possibilities are helpful.

The gingivae at the point of emergence of the tooth may become inflamed and sensitive to touch. Overambitious care by the mother should be discouraged. The inflammation will usually subside with the eruption of the tooth. Lancing of the gingivae to facilitate eruption usually aggravates the situation and is rarely indicated. A clean, smooth, firm and unbreakable teething object with which the child can aid the cutting of the gums is usually helpful.

Premature Exfoliation of Teeth. Exfoliation of the deciduous teeth is a physiologic

Table 85. Differential Diagnosis and Treatment of Dental Pain (Odontalgia)

<i>Pulpal Pain (Pulpitis)</i>	<i>Periapical Pain (Periodontitis)</i>
Sharp, lancinating and intermittent. Aggravated at night when lying down Not tender to percussion	Dull, throbbing ache
Difficult to localize. Pain may be referred to any other tooth	Tender to percussion; tooth feels high and strikes first in occlusion Easily localized
Very sensitive to changes in temperature and to sugar No swelling	Relieved by heat or cold Swelling may occur as a localized "gum boil" or generalized swelling of face
TREATMENT	
Remove carious material and food debris and insert eugenol on cotton pellet or, preferably, in zinc oxide paste	Apply heat or counterirritation (3 per cent iodine) to localize infection in oral vestibule Incise and drain (do not use local anesthesia)

process. Premature exfoliation of teeth has been observed in association with a skeletal disorder resembling rickets and an almost complete lack of plasma alkaline phosphatase activity (see p. 1224).

## DISTURBANCES IN ATTRITION OF TEETH

Attrition, the normal wearing of the teeth, begins as soon as the opposing teeth come into occlusion. The amount of attrition varies with the physical composition of the food. Deciduous teeth wear somewhat faster than permanent ones.

*Night grinding (bruxism)* results in especially rapid attrition. Bruxism should be regarded as a symptom of emotional disturbance in the child, and the cause sought. It frequently occurs in patients with cerebral palsy. Subclinical nutritional deficiencies should also be considered.

## DENTAL CARIES

Dental caries is a progressive lesion of the calcified dental tissues (enamel, dentin or cementum) characterized by loss of tooth structures.

**Etiology.** Irrespective of the many factors which influence the rate of caries progress, all available evidence points to bacteria as the active etiologic factor.

The bacteria involved are generally classified into three groups according to the role they play in the production of dental decay: (1) acidogenic and aciduric organisms, which produce the acids upon the tooth surface that decalcify the hard tissues, *Lactobacillus acidophilus* and certain streptococci being the most frequent ones; (2) proteolytic organisms, which digest the organic matrix after its decalcification and produce the characteristic discoloration and odor of caries; and (3) leptotrichiae organisms, which apparently play no primary role, but form plaques on the smooth surfaces of the teeth where acidogenic and proteolytic organisms are harbored.

**Contributory factors.** **AGE.** Although no age is immune to dental decay, caries is primarily a disease of childhood and adolescence. The periods of greatest carious activity are five to eight years in the deciduous dentition and twelve to eighteen years in the permanent dentition. The latter is the period of highest susceptibility, when 90 per cent of all rampant caries occurs.

**DIET.** The most important factor contribut-

ing to dental decay is excessive ingestion of sticky refined carbohydrates *between meals* which remain on the tooth surface for long periods of time. Acidogenic bacteria quickly produce acid from these sugars. Sugars ingested at mealtime are not as injurious, since the buffering capacity of the saliva tends to neutralize the acid.

**ORAL HYGIENE.** Lack of oral hygiene provides the food (debris) upon which the bacteria feed.

**STATE OF HEALTH.** Saliva is normally bacteriostatic, but in adverse systemic conditions the quality of the saliva as well as its quantity may be altered so that caries activity is increased. The majority of persons with chronic debilitating diseases have an increase in caries activity. In such cases oral hygiene after each meal is even more important and necessary than in the healthy person.

**Clinical Manifestations.** Caries occurs most often in areas where food debris may become impacted and stagnate, as in the pits and fissures on the occlusal surface of the posterior teeth (pit and fissure decay), less often at the contact areas between the teeth (interproximal decay) and at the neck of the tooth (gingival decay), usually only in badly neglected mouths.

The carious lesions may be acute and penetrate rapidly through the substance of the tooth, or their progress may be intermittent and slow and may even become arrested. Rapidly burrowing caries is characteristic in children; the slow, intermittent caries predominates in middle age.

**Prevention.** Since dental caries is a disease of a tissue which cannot regenerate or repair itself, the disease is likely to be cumulative. It is sometimes self-limiting (arrested caries), but never self-reparative. Caries can usually be treated adequately by the dentist and can be kept minimal by good oral hygiene and an adequately balanced diet. Simple caries is merely a problem of early detection and repair by the dentist. Neglected caries is usually a problem in oral hygiene.

Because new carious lesions appear suddenly and in numerous areas and since the lesions progress rapidly, *the usual six month interval between dental examinations is inadequate for the rapidly growing child*; examinations, particularly of the teen-age child, should be made at least at two to three month intervals. If special care is not observed during this period, extensive decay will occur with disastrous results, which will be reflected throughout adulthood.

Fluorine inhibits enzymatic activity and thus prevents bacterial action and may reduce the progress of caries at the *site of action* if present in sufficient concentration. Fluorine may be ingested in small amounts in the communal drinking water or may be applied topically by the dentist.

The physician can help to minimize dental problems in children if he will:

Encourage frequent visits to the dentist.

Discourage between-meal eating of all foods and candies containing refined sugars; and substitute fresh fruits.

Encourage brushing the teeth or at least rinsing the mouth immediately after each meal.

Encourage the application of topical fluorides on newly erupted teeth or the fluoridation of the communal water supply.

### PERIAPICAL INFECTION

**Routes of Infection.** If dental caries is allowed to progress unchecked, an infection of the pulp is inevitable. Pulpal infection spreads through the apical foramen into the surrounding periapical tissues. Such periapical infections, when not localized by natural or artificial means, may spread (1) directly, (2) along fascial planes, (3) by the lymphatics, and (4) through the venous system.

**Direct extension** may be by invasion and infection of the bone (osteomyelitis) or adjacent structures such as the maxillary sinus, the orbit, the floor of the nose and the ethmoids, and the floor of the mouth, which may result in parapharyngeal space infections.

**Fascial planes are potential spaces** which are ideal sites for the collection of pus and the development of cellulitis. The spaces most commonly involved in dental infections are (a) the masticatory, temporal and parotid spaces in the cheek, (b) the floor of the mouth (sublingual space), submaxillary space and the carotid sheath in the neck, and (c) the pharyngomaxillary (parapharyngeal) space in the pharynx.

**The lymphatics** of the periodontal structures drain into the submaxillary lymph nodes, except those from the lower anterior region, which drain into the submental lymph nodes and then into the deep cervical ones. Periapical infections may therefore cause a lymphadenitis, and, if the infection is virulent, cellulitis may result. Sinus tracts

may be formed which perforate the skin, especially in the submandibular area, and continue to drain until the infected tooth is removed and the soft tissue infection is eradicated by antibiotic therapy.

**Blood-borne** bacteria from peripheral and focal infections may be responsible for localized lesions in other parts of the body.

**Periapical infections** of the upper anterior teeth (particularly in children) may involve the lip or floor of the nose and extend by way of the anterior facial vein to the cavernous sinus. Infections of the posterior teeth may invade the pterygoid plexus of veins and by retrograde extension reach the cavernous sinus. About 4 per cent of the fatal cases of thrombosis of the cavernous sinus in children are of dental origin. The dangers of spreading a mild infection of the upper lip or nose by "squeezing" or "picking" are well known; the fact that periapical infection of the upper anterior teeth may follow the same route is less appreciated.

**Treatment.** The majority of periapical infections point into the oral cavity, owing to the warm and moist environment. Nature can be aided by increasing the intraoral heat by means of hot mouth washes. Extraoral heat may favor the spread of the periapical infection into the cheek, leading to perforation of the skin and a disfiguring scar. Antibacterial therapy is the most effective means for the control of these infections. The oral surgeon should be consulted as early as possible, since removal of the tooth permits maximal drainage of the infection.

**Dental Infections and Systemic Disease.** At one time teeth were overemphasized as foci of infection, and there were many unwarranted extractions. It is well to realize, however, that dental infections may on occasion provide a focus for systemic disease. Periapical infections in children constitute the major dental foci from which infections may spread. In adults gingival disease constitutes another source of dentogenic infections.

Many diseases cannot be successfully treated if the child has an infected tooth or a spreading periapical infection; hypochromic anemia and diabetes mellitus are examples. Because transient bacteremia is frequently associated with dental extractions, prophylactic antibacterial therapy, preferably with penicillin, is indicated when this procedure is to be undertaken.

## DISTURBANCES OF THE FACE AND JAWS

### MALOCCLUSIONS OF THE TEETH

Normal occlusion of the teeth and jaws is essential to a pleasing appearance and to efficiency in mastication. Abnormal occlusion may result from abnormal positioning of the teeth alone or from an abnormality in the growth of the jaws.

**Physiologic Spacing of the Anterior Teeth.** Fortunately, malocclusion is not common in deciduous teeth. The spacing of the anterior deciduous teeth by about four to six years of age is a physiologic condition and should not be mistaken for malocclusion. Similarly, the newly erupted permanent anterior teeth are often "spaced," incorrectly inclined, and even partially rotated when they first erupt. This condition is temporary and is self-corrected through the action of the tongue and labial-buccal musculature.

During the transition from deciduous to permanent dentition (from six to twelve years) the permanent teeth often appear disproportionately large and are frequently crowded or "spaced" and abnormally inclined. These conditions are usually self-corrective and merely represent a transitory stage in the development of dentition. It is often difficult to determine whether progress will be toward the normal or the abnormal. In case of doubt an orthodontist should be consulted.

Malocclusions of the teeth are frequently caused by (1) premature extraction of teeth, particularly the deciduous molars and the first permanent molar; (2) prolonged retention of deciduous teeth which prevents their permanent successors from coming into correct position; (3) thumb-sucking, which interferes with the normal molding action of the tongue and lips; and (4) mouth-breathing, which may disturb the formation of the jaws.

**Effects of Loss of a Tooth.** The dental arch is not static, but is in a state of dynamic balance. The removal of a single element upsets this equilibrium. The first permanent molar is the keystone of the dental arch. The extraction of the lower one without immediate replacement, especially after eruption of the second permanent molar, may result in shifting of the teeth, malocclusion, periodontal injury and caries.

The deciduous teeth serve not only in the mastication of food, but also as space main-

tainers for their permanent successors. The effects of early loss of a deciduous cuspid or molar tooth may be disastrous, since malocclusion of the entire permanent arch may result. The loss of deciduous incisors rarely has serious consequences.

**Thumb-Sucking.** The orthodontist, the pediatrician, the psychiatrist, the teacher and the parents are all concerned with the problem of thumb- or finger-sucking in a child. It may be considered a normal habit in the first two years of life, but should gradually be given up by the end of this period except on occasions of fatigue or unusual emotional disturbance. Its persistence beyond the third year usually reflects a problem in emotional development (see p. 77). Occasionally a child who has given up thumb-sucking regresses to such behavior when emotional disturbances develop (for example, after the appearance of a newborn sibling). When the habit persists abnormally, the sucking is usually vigorous and may therefore distort the deciduous dental arch. It is usually more effective to direct attention toward relieving the emotional disturbance than to call attention to the habit. In unusually severe cases psychiatric consultation may be necessary. If help is effective and thumb-sucking ceases before the sixth year, the dental deformity will be remolded and corrected in about 75 per cent of all cases.

If thumb-sucking continues after six years of age, the dental deformity which may result is usually severe, since the incisors are newly erupted and the entire anterior segment is easily displaced. Efforts to correct the underlying psychologic disturbance should continue while orthodontic care is undertaken.

**Mouth-Breathing.** The consequences of mouth-breathing are more serious to the health of the child and to the development of his teeth and jaws than those of thumb-sucking. The effects of thumb-sucking rarely extend beyond the dental arches, but mouth-breathing may affect the entire facial skeleton. The face becomes markedly elongated and narrowed because of the dropping of the mandible into an open position and because of the constriction of the upper arches and palate. The nostrils become narrowed and pinched from disuse. The facial expression becomes dull and drawn.

The tongue, assisted by the labial and buccal musculature, is nature's orthopedic appliance for correct molding of the dental arches. When the child has normal nasal function, the tongue lies against the palate, within and supporting the upper arch, so that symmetrical molding of the arch results. The lower arch lies within the upper one and is molded by it.

In the child whose normal nasal function is obstructed so that he is obliged to breathe through his mouth, the following changes may occur:

1. The gingivae frequently are hypertrophied and inflamed in the cuspid-to-cuspid region.
2. The tongue is suspended between the arches or on the floor of the mouth instead of on the roof, so that the molding action of the tongue is lost to the upper buccal segments, leaving them unopposed to the action of the buccal musculature.
3. The maxillary arch becomes V-shaped, owing to contraction of the buccal segments and protrusion of the anterior teeth. The palate seems high as a result of contraction of the alveolar arches.

Mouth-breathing may result from nasal obstruction or from habit. It occurs most frequently in long-faced (dolichofacial) persons in whom the pharyngeal space is normally long and narrow.

Infants and young children normally sleep with the lips apart; this should not be confused with the mouth-breathing habit. The physician should test for mouth-breathing with a wisp of cotton.

*Treatment* consists in surgical removal of the obstruction and in muscular exercises to strengthen the lips and to maintain closure. Orthodontic treatment is frequently necessary to make the closed-mouth position comfortable.

## FACIAL ASYMMETRY

Molding of the head during birth is possible because the bones of the cranium are not fused and can override. No such mechanism of adjustment to the narrow birth canal is present in the face. The mandible is the only movable bone in the face and is attached to the cranium only at its condylar head by the muscles of mastication. Facial asymmetries resulting from excessive molding of the cranium or from displacement of the mandible during breech or face presentations are fairly common and are usually self-correcting. Facial asymmetry resulting from injury to the growing cartilage of the condylar head during birth, infancy or early childhood is also common, but the effects may be more permanent. Traumatic injuries may occur during

birth from the placing of obstetrical forceps over the area, or may result from blows on the chin during infancy and childhood.

Such injuries, acute infections or rheumatoid arthritis of the growing condylar cartilage may result in a partial (fibrous) or complete (bony) *ankylosis of the temporomandibular joint* and failure of that side of the mandible to grow. The normal side, meanwhile, continues to grow and pushes the midline toward the affected side. The midline deviation is exaggerated during mouth opening. Roentgenograms of the affected side reveal a markedly increased pre-angular notch. Bilateral injuries to the growing cartilage result in failure of the mandible and chin to grow downward and forward, causing the entire mandible to be considerably smaller than normal and markedly distorted.

## FRACTURED INCISORS

Injuries to the anterior teeth, especially protruding upper incisors, are frequent in children. Even a minor blow to the teeth should be cause for careful observation, since the tooth often turns dark later, indicating hemorrhage into the pulp. Every traumatized tooth should be x-rayed. Chipping of the enamel may not require treatment, but fractures which expose the dentin should be covered with a sedative dressing, or the exposed dentin will become sensitive and death of the pulp may result. If the pulp is exposed, immediate capping is imperative. Even a dislodged tooth can be reimplanted if it is done immediately. Removal of the dead pulp and sealing the root canal are essential to success. A delay of more than twenty-four hours will usually result in resorption of the root and loss of the tooth. Prevention of injuries to the teeth during contact sports can be accomplished by wearing a moulded mouthguard. Discolored or fractured upper incisors present cosmetic problems and may be associated with psychologic problems.

## CLEFT LIP AND CLEFT PALATE

### (HARELIP)

Fusion of the maxillary and premaxillary processes normally occurs between the fifth and eighth weeks of intrauterine life; the palatal processes fuse approximately one month later. A failure in fusion may result in a cleft lip and/or cleft palate.

The incidence of cleft lip or cleft palate is approximately one per 800 population.

The cause is not known, although studies have indicated a genetic influence in many cases. Animal studies suggest that a variety of other influences may also be responsible for clefts if applied at a critical organogenetic period in a susceptible host. Associated congenital deformities may occur in any of the other organ systems developing at the same time with a higher incidence in the structures derived from the first branchial arch.

### CLEFT LIP

Cleft lip is more frequent in males than in females and may vary from a small notch in the vermilion border to a complete separation extending into the floor of the nose. Clefts may be unilateral (more often on the left side) or bilateral and usually involve the dental ridge. Deformed, supernumerary or absent teeth are additional anomalies. The nasal alar cartilage may also be displaced or deformed, producing a noticeable deformity of the nasal orifice. Bilateral clefts of the lip are frequently associated with a deficiency of the columella and an elongation of the vomer producing a protrusion of the anterior aspect of the cleft premaxillary process (Fig. 184).

Operation should be performed by a qualified plastic surgeon. The operation is usually performed at a month or two of age, but only after the infant is stabilized, gaining weight satisfactorily, and is free of any oral, respiratory or systemic infection.

There are several standard methods for repair of the cleft lip. The most common technique utilizes a staggered suture line to minimize notching of the lip from retraction of scar tissue. A Logan clamp, which is a wire bow attached by adhesive to the cheeks, is applied immediately after operation to take tension off the suture line. The initial operation in early infancy may be followed by revisions at four to five years of age. In most instances corrective surgery on the nose is better delayed until the teen-age period. The cosmetic results are dependent upon the extent of the original deformity, absence of infection and the skill of the surgeon.

### CLEFT PALATE

**Types.** Clefts of the palate may occur alone or in association with cleft lip. The former is more frequent in females than in males. Isolated cleft palate occurs in the midline and may involve only the uvula or extend into or through the soft and hard palates to the incisive foramen. When asso-

ciated with cleft lip, the palatal defect may involve the midline of the soft palate and extend into the hard palate on one or both sides, exposing one or both of the nasal cavities as a unilateral or bilateral cleft palate.

An isolated cleft palate may occur in association with an abnormally small mandible (Pierre Robin syndrome). There is commonly a glossoptosis, which results in a partial respiratory obstruction.

**Management.** The immediate problems of the infant with a cleft lip and/or palate are concerned with feeding and prevention of aspiration and infection. Most infants can be adequately managed by feeding them in an upright position, using softened nipples with slightly enlarged nipple openings. A lamb's nipple may be of value. In some instances a medicine dropper or gavage feedings may be used to advantage. Special cleft palate nipples and plastic palatal coverings are not necessary.

**Surgery.** In the past, palatal operation was often performed in infants less than one year of age. Not infrequently such early operation resulted in a deformed maxillary arch, especially when multiple palatal operations were necessary or excessive scarring was produced. At present the tendency is to delay operation so that the surgeon can take advantage of the palatal changes which occur with growth. Since clefts of the palate vary considerably in size, shape, and degree of deformity, the timing for operation should be individualized. Criteria such as width of the cleft, adequacy of the palatal parts, the morphology of the surrounding areas (such as the width of the oropharynx) and the

FIG. 184. Double cleft lip and cleft palate in an infant 2 months of age. Note the intermaxillary process between the clefts.

neuromuscular function of the soft palate and pharyngeal walls should affect the decision. The goals of operating are union of the cleft parts, intelligible and pleasant speech, and avoidance of injury to the growing maxilla. The optimal time for palatal surgery varies from one to five years of age. When operation is best delayed beyond the third year, a dental speech appliance can be prescribed to help the child develop intelligible speech.

**PREOPERATIVE AND POSTOPERATIVE MANAGEMENT.** Even the suspicion of any existing infection is a contraindication to operation. Bleeding and clotting times should be determined before the operation. If the child is in good nutritional state and in fluid and electrolyte balance, feeding may be permitted to within six hours of the operation. Fluid therapy is discussed on page 195.

During the immediate postoperative period *special nursing care is essential*. Gentle aspiration of the nasopharynx minimizes the hazards of the common complications of atelectasis and/or of pneumonitis. The primary considerations in the postoperative care are maintenance of a clean suture line and elimination of strain on the sutures. For these reasons the infant is fed with a medicine dropper, and the arms are restrained with elbow cuffs. A fluid or semifluid diet is maintained for three weeks, and feeding is with a dropper or spoon. The patient's hands as well as toys and other foreign bodies must be kept away from the palate.

**Complications.** Recurrent otitis media and hearing loss are frequent complications. Excessive dental decay is not unusual and requires special care. Displacement of the maxillary arches and malpositions of the teeth usually require orthodontic correction.

**Speech.** Speech defects may be present even after good anatomic closure of the palate. Such speech is characterized by emission of air from the nose and by a quality of hypernasality when certain sounds are made. The speech defect before and, at times, after palatal surgery is due to inadequacies in function of the palatal and pharyngeal muscles. The muscles of the soft palate and the lateral and posterior walls of the nasopharynx constitute a valve which functions to separate the nasopharynx from the oropharynx during swallowing and in the production of certain sounds. If the valve does not function adequately, it is difficult to build up enough pressure in the mouth to make such ex-

plosive sounds as p, b, d, t, h, g or the sibilants s, sh, ch, and such words as "cat," "boats" and "sisters" are not intelligible. After operation or the insertion of a speech appliance it may be necessary to institute speech therapy to lessen the persisting speech defect.

A *complete program of habilitation* for the child with a cleft lip and/or palate may require many years of special medical, surgical, dental and speech treatment. Representatives of the specialties involved function more effectively on a team basis than individually.

A pediatrician, plastic surgeon, otolaryngologist, children's dentist, prosthetic dentist, orthodontist, speech pathologist, medical social worker, psychologist, child psychiatrist and public health nurse may make up such a *cleft palate team*. The child's physician may need to avail himself of such a group, usually located in the larger medical centers; most states have programs for financial assistance for the medical care when the economic status of the family warrants. Parental counselling by the physician and members of the cleft palate team is an important aspect of care.

## PALATOPHARYNGEAL INCOMPETENCE

The speech disturbance characteristic of the child with a cleft palate can also be produced by other osseous or neuromuscular abnormalities in the oral and pharyngeal areas. The common denominator is the inability to form an effective muscular seal between the oropharynx and nasopharynx during swallowing or phonation. The anomaly may be in the bony structures of the palate or pharynx or in the muscles attached to these structures. An adenoidectomy may precipitate the speech defect in a child who previously spoke normally, and the defect may be attributed to a previously unrecognized submucous cleft palate. In such instances it is assumed that the adenoid had a static function as a mass protruding into the epipharynx, allowing the soft palate to make contact with it when elevated; this became impossible after removal of the adenoids. If there is sufficient reserve neuromuscular function, compensation in palatopharyngeal movement may take place and the speech defect disappears, although often some symptoms of palatopharyngeal incompetence may persist. In other instances slow involution of the adenoids may allow for gradual compensation in palatal and pharyn-

geal muscular function. This may explain why a speech defect does not become apparent in some children who do have a submucous cleft palate or similar anomaly predisposing to palatopharyngeal incompetence.

#### *Organic Factors Producing Palatopharyngeal Incompetence*

- I. Congenital anomalies (alone or combined)
  - A. Overt cleft palate
  - B. Submucous cleft palate
  - C. Hypoplasia of hard and/or soft palate
  - D. Extreme variations of nasopharyngeal space
    1. Depth factor—occipitalization of the atlas (platybasia)
    2. Width factor—widespread pterygoid plates
  - E. Intracranial defects with motor impairment of the palatopharyngeal muscles
- II. Acquired disturbances
  - A. Loss of palatal tissue due to infection, trauma or malignancy
  - B. Neuromotor disorders
    1. Bulbar poliomyelitis
    2. Brain injury due to infection, trauma, malignancy or vascular disease
- III. Associated or precipitating factors
  - A. Acquired disturbances superimposed on congenital anomalies
  - B. Adenoidectomy
  - C. Changes in structure with growth
 

The palate is gradually positioned lower in the oral cavity with growth changes. In the adolescent and adult soft palate contact with the pharynx occurs below the adenoid mass
  - D. Inadequate muscular compensation, especially following adenoidectomy or growth changes

#### *Manifestations of Palatopharyngeal Incompetence*

1. Hypernasal speech defect especially noted in the articulation of pressure consonants, such as p, b, d, t, h, v, f, s
2. Conspicuous constricting movement of the nares during speech
3. Inability to whistle, gargle, blow out a candle or inflate a balloon
4. Loss of liquid through the nose when drinking with the head down
5. Otitis media and hearing loss

#### *Signs on Oral Inspection*

1. Cleft palate or a relatively short palate with a large oropharynx
2. Absent, grossly asymmetric or minimal muscular activity of the soft palate and pharynx during phonation or gagging
3. A submucous cleft, as evidenced by the following pathognomonic signs
  - (a) Bifid uvula
  - (b) Translucent membrane in midline of soft palate revealing lack of continuity of muscles

- (c) Palpable notching in posterior border of hard palate instead of a posterior nasal spinous process
- (d) Forward or V-shaped displacement of grooving on the soft palate during phonation or gagging

The *symptoms* of palatopharyngeal disturbances are largely similar, although clinical signs will vary. The *diagnosis* can usually be made without difficulty if there is sufficient awareness of the entity. Palatopharyngeal incompetence can be demonstrated roentgenographically. The head should be carefully positioned to obtain a true lateral view; one film is obtained with the patient at rest and another during continuous phonation of the vowel "u" as in "boom." The soft palate contacts the posterior pharyngeal wall in normal function, while in palatopharyngeal incompetence such contact is obviously absent.

*Treatment* of palatopharyngeal incompetence is either surgical or prosthetic. In selected cases the palate may be retropositioned or a pharyngoplasty performed, utilizing a flap of tissue from the posterior pharyngeal wall. Dental speech appliances have also been used successfully. *Adenoidectomy should be avoided when there is a submucous cleft palate or a potential palatopharyngeal incompetence.*

### **HYPOPLASIA OF THE MANDIBLE**

The congenital deformity of an abnormally small mandible is not uncommon. The defect may be symmetric or asymmetric. The asymmetric variety is generally associated with other congenital anomalies on the same side, such as a small ear lobe. The mandibular ridge fails to contact the maxillary ridge and rests within the contour of the hard palate, producing a typical "Andy Gump" type of deformity. Apart from the cosmetic aspects, there are problems associated with respiration and feeding.

When the hypoplasia is marked, the tongue may be displaced posteriorly (glossoptosis) and partially obstruct respiration. When a cleft palate is associated, it is known as the Pierre Robin syndrome.

In relatively mild cases the infant may be placed in the prone position to alleviate the respiratory distress. If the feeding is undertaken carefully and slowly, improvement may occur with growth. Although a variety of splints and traction devices have been de-

signed to pull the mandible forward, they have not been successful. In extreme situations, where obstruction of the airway is nearly complete, performance of a tracheotomy may be necessary. If adequate respiration and nutrition are established, sufficient mandibular growth usually occurs within a few months to relieve the glossoptosis and permit removal of the tracheotomy tube. Suturing of the tongue to the lower lip (Beverly Douglas) may be helpful in the less severe cases. Since these patients have potentialities for mandibular growth, plastic surgical procedures are preferably delayed and are often unnecessary.

Unilateral hypoplasia of the mandible is sometimes part of an anomaly complex that includes partial paralysis of the facial nerve, macrostomia, blind fistulas between the angles of the mouth and the ears, and deformed ear

lobes. Because of the absence or hypoplasia of the mandibular condyle on the affected side, severe facial asymmetry and malocclusion develop. Experience has indicated that when there is early roentgenographic evidence of congenital condylar deformity, the deformity will increase with age. Plastic surgical procedures may be indicated early to minimize the deformity.

The symmetric mandibular deformity in mandibulofacial dysostosis (Treacher-Collins syndrome; Franceschetti-Klein syndrome) differs from the Pierre Robin syndrome in that the over-all shape of the mandible is grossly deformed and is associated with other facial anomalies. Furthermore, in mandibulofacial dysostosis there is no basic improvement in facial appearance as mandibular growth proceeds. Plastic surgical procedures are indicated to minimize the deformity.

## DISEASES OF THE GUMS AND GINGIVAE

The gingivae cover the necks of the teeth and are continued as the gums over the alveolar bone holding the teeth.

Gingivitis may be caused by local irritants or trauma, such as calculus, food debris or malocclusion; by systemic conditions such as acute infectious diseases, deficiency states and blood dyscrasias; or by a combination of local and systemic conditions. Gingival disease, if neglected, gives rise to periodontitis and periodontoclasia (pyorrhea). In the adult more teeth are lost as a result of periodontal diseases than as a result of caries. Gingivitis is rare in the healthy child, but common in the adult and in the sick child.

A transient gingivitis sometimes occurs when the deciduous tooth first erupts (*eruption gingivitis*); it is much less common with the eruption of the permanent teeth. The marginal gingival collar surrounding the tooth is often the site of inflammatory lesions in *vitamin C deficiency* and in *gingival drug reactions* such as those associated with Dilantin therapy.

*Crowding of the teeth* causes pressure upon the interdental papillary gingivae. In children this often leads to inflammation and hypertrophy of the gingival papillae. These areas become even more severely inflamed and hypertrophied when systemic factors such as those previously mentioned interfere with cellular metabolism.

So-called *filth gingivitis* is usually caused by lack of oral hygiene or by local irritants. The free margins of the gingivae become inflamed, violaceous and edematous. The interdental papillae in particular become engorged and covered with an exudate. There is usually no pain. If the condition is allowed to become chronic, the gingival tissue may become hyperplastic, or the underlying alveolar bone may be invaded, and a periodontoclasia results, particularly if any systemic factor intervenes.

The impact of cold air in long-continued *mouth-breathing* results in an irritation of the oral tissues. In mild cases the gingivae merely become inflamed, but in severe cases they may become hypertrophied. The incidence is much higher in the mentally deficient with dirty mouths than in healthy children with clean mouths. The mandible is usually retruded, and a severe malocclusion is present. (See Mouth-Breathing, p. 627.)

### LATERAL ABSCESS (GUM BOIL)

A small abscess or fistulous tract may occur on the gums about the level of the apex of the tooth. It is an extension of a periapical infection. As soon as the infection is localized on the gum it should be incised and allowed to drain before the tooth is extracted.

## DISEASES OF THE ORAL MUCOSA

The term "stomatitis" is frequently used to include the various inflammatory lesions that occur in the mouth. The term is not a good one, since it implies a diffuse inflammation of the various organs and tissues of the mouth, a condition which is actually rare. So far as possible it is preferable to designate specifically the area affected—i.e., gingivitis, buccal mucositis, glossitis, cheilitis. Any infection of the gingivae, lips or tongue may extend to the oral and pharyngeal mucous membranes. Such infections are less common but more serious than infections limited to the gingivae. They are far more painful and are often attended with toxic symptoms. Thus the site of the infection is as important as the cause of the infection.

**HERPETIC STOMATITIS** (See p. 491.)

(ACUTE INFECTIOUS [HERPETIC] GINGIVOSTOMATITIS, ULCEROMEMBRANOUS STOMATITIS, APHTHOUS STOMATITIS, VINCENT'S STOMATITIS)

It would appear that a large number of the oral lesions identified by the foregoing designations are an etiologic entity produced by the virus of herpes simplex.

**OTHER APHTHOUS LESIONS****ALLERGIC APHTHAE**

Allergic persons may have repeated attacks of aphthae. In appearance and course the lesions are similar or identical to those of herpetic aphthae.

**TRAUMATIC APHTHAE**

Traumatic aphthae often result from biting the mucous membrane, from accidental injuries by toys, hard foods or the toothbrush, and from irritations by sharp edges of carious teeth and broken fillings. The lesion resembles that of herpetic aphthae, but is of shorter duration and less painful. The injured area may be covered with tincture of benzoin compound.

**BEDNAR'S APHTHAE**

Superficial abrasions or erosions on the posterior part of the hard palate in the newborn infant may be caused by mechanical abrasion. They are usually caused by the gauze-covered finger of the mother or nurse during an attempt to cleanse the infant's mouth, but

may arise from friction by the nipple. The erosions generally heal within a week after the source of irritation has been removed.

**THRUSH**

(ORAL MONILIASIS)

(See also pp. 330, 798, 1293.)

The condition known as thrush is a mild infection of the skin and mucous membranes characterized by the formation of pearly-white, curdlike lesions. It is caused by the fungus *Candida* (*Monilia*) *albicans*.

**Etiology.** *Candida albicans* (*Saccharomyces albicans*, *Oidium albicans*) is a saprophyte in the normal mouth (except in the newborn infant) until such time as tissue resistance is sufficiently impaired by improper diet or disease, at which time the organism gains a foothold and assumes a pathogenic role. Thus premature and weak infants, undernourished children and old people with low resistance are especially susceptible.

A positive relationship between maternal vaginal and infantile oral moniliasis has been demonstrated; this maternal source appears to be the principal means for infection of healthy newborn infants. Infection of other healthy newborn infants may occur from imperfectly sterilized bottles or nipples, from the mother's breast or the attendant's hands. Familial cross infection may occur via the patient's oral secretions or stools and from dust. Suppression of the natural oral flora by long-term antibacterial therapy enhances the development of moniliasis as well as other fungus infections.

**Clinical Manifestations.** The lesions which are characteristic may be found wherever warmth and moisture favor growth of the fungus (the mouth, anal region, genitals, interdigitally and under the breasts). In the mouth the lesions usually appear on the gingivae, the sides of the tongue, the buccal mucosa and the throat. The superficial, strandlike lesions become confluent and form pearly-white, elevated patches which resemble milk curds; when forcibly removed, they leave a raw surface. The lesions are painless with little or no swelling, usually self-limited, and after treatment heal within a few days by exfoliation of the epidermis.

If the infection is localized to the mouth, the systemic symptoms are mild; otherwise

FIG. 185. Gangrenous stomatitis, beginning in the lip.

they may be severe. Esophagogastritis and pneumonitis may complicate the oral infection. Extensive spread of the infection is usually the result of an underlying debilitating condition. The organism is commonly found in the lesions of *perlèche*.

**Diagnosis.** Budding yeasts and rudimentary branching filaments can be seen in fresh smears by adding a drop of 10 per cent potassium hydroxide solution. Cultures made on Sabouraud's medium are diagnostic; the filaments are long and thin, with little branching, but with short lateral buddings.

**Treatment.** At present there is no completely effective agent. Nystatin, in doses of 200,000 units per 1 ml. applied locally three to four times daily with a soft cotton swab, allowing the infant to swallow whatever portion remains, is effective in eliminat-

ing the lesions. The rate of recurrence of moniliasis following its use, however, is similar to that following such topical therapy as 1 per cent aqueous gentian violet solution and 1:1000 aqueous solution of benzalkonium chloride (Zephiran), each of which is moderately effective.

## NOMA

(GANGRENOUS STOMATITIS, CANCRUM ORIS, INFECTIVE GANGRENE OF THE MOUTH)

Noma is a relatively rare progressive gangrene of the buccal mucosa which results in a perforating ulcer of the cheek (Fig. 185).

**Etiology.** Noma is caused by invasion of the buccal tissues by fusospirochetal organisms and other bacteria in children whose resistance has been lowered by a concurrent disease or a nutritional deficiency.

**Clinical Manifestations.** The lesion usually begins as a small ulcer with few constitutional symptoms, but soon results in a gangrenous, greenish-black area on the gums, buccal mucosa or mucocutaneous borders. The tissues then become swollen and characteristically fetid. The gangrenous area spreads slowly but inexorably until the cheeks are perforated and the jaws denuded.

**Treatment.** Intensive antibacterial therapy (penicillin or other agents, the selection being based on susceptibility tests *in vitro*) should be instituted as soon as the diagnosis is made and continued until all necrotic tissue, whether soft tissue or bone, has sloughed. Since malnutrition is frequent in these patients, an adequate diet should be introduced gradually with special emphasis on adequate amounts of protein and vitamins. Parenteral fluid therapy is usually necessary in the acute stage. Plastic surgical procedures may be indicated when healing is complete.

## DISTURBANCES OF THE LIPS

### FISSURES

#### CHEILITIS

Dryness of the lips followed by scaling and cracking and accompanied by a characteristic burning sensation is common in children. It is usually caused by sensitivity to contact substances (from toys and foods) plus a photosensitivity to the sun's rays. It is aggravated by the habit of alternate wetting with the tongue and drying by the wind, especially in cold weather. Cheilitis also often occurs in association with fever.

### ANGULAR FISSURES

#### (PERLÈCHE)

Maceration and fissuring at the angles of the mouth may be caused by an infection with *Candida albicans* (*perlèche*; moniliasis, see p. 633). It is contagious, but causes no constitutional symptoms or pain. The infection usually extends inside the mouth. Treatment with a mild antiseptic is successful.

When fissuring is caused by a nutritional deficiency, it is termed *cheilosis*. Cheilosis is

an early sign in riboflavin deficiency and is often accompanied by moniliasis.

Fissuring also occurs in mentally deficient children who drool (rhagades in mongolism).

## HERPES SIMPLEX

(HERPES LABIALIS, COLD SORE, FEVER BLISTER)

Herpes simplex (see p. 490) is an aggregate of small transparent vesicles on an inflammatory base and is accompanied by itching or burning. It usually affects the mucocutaneous junction, but may affect the skin of the face or the mucous membrane of the mouth. It is self-limited, disappearing in eight to fourteen days.

## ALLERGIC ERUPTIONS

Certain substances such as lipsticks and toothpastes may produce eruptions where

they come in contact with the lips. The lesions may be vesicular or elevated reddish wheals (urticaria), and there may be a glossitis. There is usually a history of other allergic manifestations.

## ANGIONEUROTIC EDEMA

A variety of urticaria which may be responsible for a sudden diffuse swelling of short duration (one to two days) in children with allergic tendencies is angioneurotic edema. It often itches, but seldom is painful. There is no erythema, and the tissues appear to be normal in color, firm, and do not pit.

## MUCOUS RETENTION CYST

A mucous retention cyst is a single teatlike projection covered by a thinned-out mucous membrane and filled with a clear fluid. It is caused by occlusion of the orifice of a labial or buccal mucous gland, resulting in retention of the secreted fluid.

# THE TONGUE

The tongue in certain instances may assume an unusual appearance without having an undue clinical significance. The patient is often not aware of the unusual appearance.

## FISSURED TONGUE

The pattern may be foliaceous (leaflike) or cerebriform. The tongue may be somewhat enlarged and show imprints of the teeth at the sides. Fissured (scrotal) tongue is usually congenital, but may be acquired, especially in mongolism. Occasionally, fissuring may follow certain diseases such as scarlet fever, syphilis or typhoid fever.

## BLACK HAIRY TONGUE

(LINGUA NIGRA)

This condition is characterized by an elongation of the filiform papillae into hairlike projections as long as  $\frac{1}{2}$  to 1 inch. It is generally concentrated in a triangular area in front of the V-shaped line of circumvallate papillae. The patch may vary from brown to black. The condition is usually chronic, but often disappears spontaneously.

A similar condition also occurs in cases of chronic intraoral hemorrhage, as in purpura and hemophilia. The filiform papillae become hypertrophied and are colored dark brown

by the blood pigments. There is always a characteristic fetor ex ore, owing to the presence of blood in the mouth.

Hairy tongue may occur during prolonged antibiotic therapy, especially with oral troches.

## GEOGRAPHIC TONGUE

(WANDERING RASH)

This benign lesion of the tongue is characterized by one or more smooth, bright red patches often showing a yellowish, grayish or whitish membranous margin upon the dorsum of an otherwise normally roughened tongue. The patches represent areas in which the filiform papillae have become completely desquamated, leaving a smooth, slick surface. The patches may be single or multiple, discrete or confluent (maplike). They travel by an extension of desquamation of the papillae at one edge and a regeneration of the normal papillae at the other. A single cycle may last two to seven days. The condition is usually chronic and has been attributed to allergy.

Temporary smooth red patches on the dorsum of the tongue simulating geographic tongue are frequent in children with low grade fevers, particularly those accompanying the common cold and chronic systemic infections.

## TONGUETIE

A short lingual frenum making it impossible to protrude the tongue to the normal extent usually causes no symptoms and requires no treatment. In *extremely rare* instances the lingual frenum is short and fibrous and may interfere with sucking and later with articulation. Treatment consists in nicking the edge of the frenum with blunt-pointed scissors and then separating the remaining membrane.

## MACROGLOSSIA

The tongue in infants is often proportionately larger than the other oral structures because it grows at a relatively faster rate and is not confined by the teeth. In stocky infants the tongue is frequently so large and unconfined that it protrudes from the mouth, and occasionally has been mistaken for a manifestation of hypothyroidism. As the infant grows, the other oral structures gradually catch up and confine the tongue, so that its relative size is decreased.

A true hypertrophy of the tongue is rare. It may exist congenitally as a diffuse lymphangioma or as a muscular hypertrophy (rhabdomyoma). The tongue may reach such a size that it cannot be retained in the mouth, with the result that nursing and, later, speech are interfered with. In such cases the teeth are pushed into a malocclusion by the action of the tongue.

*Treatment* is surgical, although some relative adjustment usually occurs as the child grows older.

Hemangiomas and cysts may be responsible for a diffuse or localized enlargement of the tongue. Enlargement of the tongue is also present in cretinism, acromegaly, mongolism and occasionally gargoylism.

## TONGUE-SWALLOWING

See Hypoplasia of the Mandible (p. 631).

## THE TONGUE IN SYSTEMIC DISTURBANCES

The tongue reflects changes in the physical state of the body, at times in a diagnostic manner.

### WHITE COATED TONGUE

The accumulation of food debris and bacteria among hypertrophied filiform papillae

causes a *moist coated tongue*. The filiform papillae are present at birth, but are much shorter than even the fungiform papillae until about five years of age, so that the tongue appears smooth. Thus in the young child the cause should be sought for any coating of the tongue.

The condition of *furry tongue* is seen early in states of mild dehydration and low grade fever. The "fur" is actually the hypertrophied filiform papillae. The tongue seems dry.

Failure of secretion by the salivary and lingual glands results in a *dry coated tongue*. Dryness of the tongue is one of the best clinical evidences of dehydration. The color may vary from white to brown.

A transitional stage from the white coated tongue to the raw, red tongue is known as the *white strawberry tongue* (Fig. 111, p. 407). The appearance is that of an unripe strawberry. The engorged and enlarged fungiform papillae appear prominently above the level of the white, desquamating filiform papillae. It is seen early in scarlet fever and other acute febrile states.

### RAW RED TONGUE

#### (GLOSSITIS)

When the filiform papillae of the "white strawberry tongue" or the coated tongue are shed, leaving the engorged fungiform papillae raised above the smooth, denuded surface of the tongue, the condition is known as "red raspberry" or "red strawberry tongue." This is seen often in the later stages of febrile states and about the sixth or seventh day of scarlet fever (Fig. 113, p. 407).

When the papillae become flattened and edematous (mushroom-shaped), but not atrophied or shed, the *raw pebbly tongue* results. The color is a characteristic purplish-red (magenta) instead of pink. Edema of the tongue is common, and the indentations of the teeth can easily be seen. The edges of the tongue often become denuded and raw, resulting in a burning, painful sensation. Fissuring is common. Magneta glossitis occurs in ariboflavinosis in association with cheilosis, photophobia and lacrimation.

Complete atrophy of both the filiform and fungiform papillae results in a *smooth atrophic tongue*. The tongue also shrinks in size. The desquamated surface is usually dry and extremely sensitive to painful stimuli (glazed tongue). Atrophic glossitis with a fiery red (scarlet) coloration of the tongue is characteristic of niacin deficiency (pellagrous glossitis), especially when accom-

panied by infection. Atrophic glossitis with a pale salmon coloration of the tongue (Hunter's glossitis) occurs in pernicious anemia, and also in sprue, achlorhydria and hypochromic anemia.

## TRAUMA

Accidental biting of the tongue, irritation by carious teeth, injuries by sharp objects placed in the mouth, and burns by hot foods occur frequently in children. Such injuries may result in a simple blister or ulcer which disappears in a few days, but even superficial ulcers are painful. In extreme cases the tongue may become swollen and edematous; ice may be used to reduce the swelling. The food should be cool and in liquid form; it may be necessary to feed young infants

through a nasal tube. A mild antiseptic mouthwash such as 1 per cent tincture of iodine in physiologic saline solution may be used.

Accidental injuries and burns resulting from ingestion of poisons are not uncommon in young children. Immediate care is determined by the poison ingested and the extent of the injury. In severe cases particular attention should be given to adequacy of the airway; occasionally tracheotomy is essential as a lifesaving measure.

Ulcerations of the frenum and the margins of the tongue are usually the result of herpetic infection; those limited to the frenum may be secondary to biting the tongue during paroxysms of coughing in pertussis. Such ulcers have also been observed in association with familial autonomic dysfunction.

## SALIVARY GLANDS

### SALIVATION

#### (DROOLING)

The newborn infant does not secrete much saliva, since many of the cells of the salivary glands do not mature until about three to six months of age. About three months of age the flow of saliva is increased, and drooling occurs because the child has not learned to swallow it. Drooling becomes more evident with the cutting of the first teeth. Drooling is common in idiots because of failure to swallow the saliva.

### EXCESSIVE SECRETION OF SALIVA

#### (PTYALORRHEA, PTYALISM)

Excessive secretion of saliva occurs frequently in children as a reflex during the process of teething; it may also occur as a reflex to anticipated pain, from irritation of lesions in the mouth or from nausea. It is also seen after administration of mercurial compounds and in certain nervous affections such as encephalitis and chorea. In uncontrolled diabetes mellitus sugar is excreted in the saliva and predisposes to rampant caries.

### XEROSTOMIA

#### (DRY MOUTH)

Temporary dryness is relatively common. In even mild fevers, the quantity of saliva is quickly reduced. Xerostomia is often accompanied by dry, cracked and burning lips (cheilitis) and a burning sensation in the mouth, and there is often a characteristic

fetid odor. The nurse should relieve the dryness and burning by frequent moistening of the mouth with cooled liquids and by the application of a bland ointment to the lips. Measures must, of course, be taken to replenish the loss of water from the tissues.

*Congenital xerostomia* rarely occurs. The entire mouth becomes glazed and dry and filled with epithelial and food debris. The condition responds well to administration of pilocarpine, indicating a hypoplasia rather than plasia of the major salivary glands.

## ENLARGEMENTS OF THE SALIVARY GLANDS

*Malformations* of the salivary glands are rare, and *tumors* are seldom encountered in children. *Cysts* are usually the result of an obstruction of the duct by inflammation or stone. *Hemangioma* is the most common tumor of the parotid gland in infants and children and is treated by surgical excision.

### SUPPURATIVE PAROTITIS

#### (INFECTIOUS PAROTITIS, SECONDARY PAROTITIS)

Hematogenous or retrograde (through Stensen's duct) infection is not an uncommon complication in weak, poorly nourished children, and may occur in infants during the first week of life. Prematurity of birth and trauma to the oral tissues and salivary glands

in delivery or resuscitation may be contributing factors. *Staphylococcus aureus* seems to be the most frequent pathogen.

The process is usually unilateral. The gland becomes swollen, tender, inflamed and painful. If the child's general condition improves rapidly, resolution usually occurs in a few days. However, if therapy is ineffective, a deep-seated suppurative process can develop which may lead to necrosis of the upper jaw and terminate in death from sepsis.

*Treatment* should be prompt and continuous. Specific antibacterial therapy is of greatest importance. For older children warm, saline mouth washes are helpful and should be supplemented by hot wet packs extraorally until the pus is evacuated through Stensen's duct or the buccal mucosa. Intraoral localization is important to prevent facial scarring. When there is fluctuation and the abscess does not drain spontaneously, surgical incision is required.

### RECURRENT PAROTITIS

Recurrent swelling of the parotid gland in otherwise healthy children from the ages of eight months to twelve years constitutes a fairly characteristic clinical syndrome. The condition is not associated with any systemic disease or any local condition in the mouth and is not contagious. The swelling is usually unilateral, although both parotid glands may be involved simultaneously or at alternate intervals. Ten or more recurrences may be observed in an individual child. There is little pain associated with the swelling, which is limited to the parotid glands. The duration of swelling is usually two to three weeks; subsidence is spontaneous and may be complete or partial. The incidence appears to be higher in the spring. Allergy and spasm of Stensen's ducts have been postulated as etiologic factors, but there is no proof.

No specific therapy is known. Surgical drainage is usually unnecessary. Antibacterial therapy may shorten the attacks and should be selected on the basis of bacteriologic findings. Roentgen therapy has been used and seemed to shorten the attack and to decrease the number of recurrences. Owing to radiation hazards in a growing child, this should be considered only in difficult cases.

### RANULA

This term is applied to a retention cyst of the sublingual and occasionally of other salivary glands in the floor of the mouth. The retained saliva pushes up the mucosa of the mouth, giving it the appearance of a frog's belly. The occlusion of the sublingual duct may be caused by a plug composed of bacteria and many thread-forming organisms (*Leptothrix*) or by concretions of calculi (*sialolithiasis*) in the salivary ducts. A secondary infection or abscess formation occasionally occurs. Complete resection of the cyst wall is the only satisfactory method of treatment.

### MIKULICZ'S DISEASE

This is a term applied to bilateral, painless enlargements of the parotid and lacrimal glands of unknown etiology and usually associated with dryness of the mouth and an absence of tears. These manifestations may also occur as a syndrome in specific diseases such as tuberculosis, leukemia and lymphosarcoma.

## TUMORS OF THE NECK

For other swellings of the neck, see Goiter (p. 1169), Diseases of the Lymph Nodes (p. 991), Tuberculosis (p. 466) and Mumps (p. 505).

### THYROGLOSSAL DUCT CYST

A thyroglossal duct cyst may be located anywhere from the base of the tongue at the foramen caecum to the isthmus of the thyroid gland along the course followed by this gland in its descent into the neck. Usually the duct atrophies; when it does not do so, a cystic swelling may appear superficially, usually in the midline of the neck just below the hyoid bone. The swelling usually develops before puberty as a painless, progressively enlarging, movable mass. The cyst moves upward when the tongue is protruded or during swallowing. The cyst may become infected during the course of an upper respiratory infection and may rupture spontaneously. Recurring inflammation or a discharging fistula cause the patient to seek medical attention. The discharge is intermittent and slight except when activated by infection. The cyst and the entire tract, including the midportion of the body of the hyoid bone, must be completely excised to the base of the tongue. Incision and drainage are at all times contraindicated.

### BRANCHIAL CLEFT CYST

(LATERAL CERVICAL CYST)

The branchial cleft cyst is found in the neck anterior to the sternocleidomastoid muscle, but, in contrast to the thyroglossal duct cyst, not in the midline. The branchial cleft cyst represents a remnant of a right or left branch of a branchial cleft. Although the cyst may not be recognized until adolescence, it or its anlage has been present since birth. It grows slowly, is oval-shaped and may become extremely large. It is usually smooth, fluctuant, moderately movable and may be attached to the skin.

The cyst is sometimes mistakenly diagnosed as an abscess and incised and drained. Injection of radiopaque substances into the fistula may reveal a tract opening into the tonsillar area, and the patient may complain of a bitter taste. Incision and drainage, curettage and the use of caustics only result in the establishment of a fistula. The cyst should be excised completely.

## THE ESOPHAGUS

Symptoms suggestive of esophageal disease in infants and children are dysphagia, complete inability to swallow, pain on swallowing, regurgitation of undigested food or fluids, and hematemesis. The esophagus may be examined directly with the esophagoscope and roentgenographically. Barium is the usual contrast medium used for roentgen examinations unless a tracheo-esophageal fistula or a complete esophageal obstruction is suspected, when an iodized oil should be used to avoid aspiration of barium into the trachea or bronchi. An esophagoscopic examination can

be made without anesthesia at any age.

## CONGENITAL ANOMALIES

The esophagus is developed from the first part of the primitive gut, its upper part from the retropharyngeal segment, and the lower from the pregastric segment. As the neck differentiates and the heart and lungs push the stomach caudad, the esophagus elongates rapidly. Vacuoles appear by the eighth week in the epithelium to form a lumen. During the fourth week the laryngotracheal groove develops to become the larynx and trachea and the primordia of the lungs. Two furrows course longitudinally along the sides of this respiratory primordium and cut inward deeper and deeper until they separate it from the esophagus. This separation progresses in a cephalic direction, the lung bud first becoming free. Congenital anomalies develop through a failure of one of these critical steps to be completed correctly, and vary from complete absence of the esophagus to duplication throughout its length.

### ATRESIAS AND FISTULAS

**Etiology.** Atresias are the most common of the congenital anomalies and result from failure of the pharyngeal and gastric outpouchings to unite or establish a satisfactory lumen. These defects may be due to a mechanical development deviation of the septum between the trachea and esophagus, or to altered cellular growth along the septum. Absence of growth along the septum results in a fistula to the trachea, and deficient growth of entodermal cells of the dorsal wall of the foregut results in atresia.

**Clinical Forms.** Of the four principal types of complete atresias (Fig. 186), the most common (90 per cent) consists of an upper segment which ends in a blind pouch about the level of the bifurcation of the trachea or slightly above it, and a lower segment from the stomach which is connected to the trachea by a short fistulous tract. The *symptoms* are characteristic. The first swallow or two by the newborn infant is normal; then suddenly the fluids return through the nose and mouth; the child coughs, struggles, turns cyanotic and may stop breathing. The cycle is repeated with each attempt at nursing, and between feedings there is a constant drooling from the dependent corner of the mouth. The stomach becomes distended with air, and bile and gastric secretion may be collected from

FIG. 186. Diagrams of the 4 most commonly encountered anomalies associated with congenital atresia of the esophagus in order of frequency. 1, (90%) Upper blind sac, lower esophageal segment communicating with the trachea to permit air to enter the stomach. 2, Both upper and lower esophageal segments are blind. No air enters the stomach; this is of considerable clinical significance and is apparent on the roentgenographic film, since no gas is visible below the diaphragm. 3, Upper segment communicates with the trachea, lower segment blind. Asphyxia usually occurs with the first attempt at feeding. 4, Both upper and lower segments communicate with the trachea.

the regurgitated material, owing to the fistula between the lower segment and trachea.

In the second commonest type both segments are blind, neither being connected to the air passages. The *symptoms* are like those of the first type, but the roentgenogram shows an opaque abdomen devoid of the usual gas bubbles in the stomach and intestines. Since no gastric juice can enter the tracheobronchial tree, the pulmonary symptoms are produced entirely by overflow of milk and saliva from the esophagus, so that postural drainage and catheter or bronchoscopic suction of the trachea are effective in clearing the obstruction. The lower segment is often rudimentary, and generally primary anastomosis is difficult to accomplish.

In the third type the upper segment opens into the trachea, and the lower is a blind pouch. In this type the infant may "drown"

with the first feeding, or a fatal aspiration pneumonia develops within a day or two.

*Tracheo-esophageal fistula without atresia*, the so-called H type (Type 4, Fig. 186; Fig. 187), is a relatively rare but important anomaly. It may be suspected in infants who show signs of respiratory embarrassment, and choking and coughing associated with feedings. There is usually gastric distention. There may be excessive amounts of mucus in the oropharynx, and repeated episodes of pneumonitis are common. The diagnosis is established endoscopically and roentgenographically by using contrast media; techniques have been described (see References). The fistula may be found at any point from the level of the cricoid cartilage to the mid-esophagus. The opening is usually at a higher level in the trachea than in the esophagus. Treatment is surgical.

**Diagnosis.** The diagnosis of congenital atresia is evident from the difficulty in swallowing, choking, cyanosis or regurgitation with the first or second swallow of food, and may be confirmed by roentgenologic, catheter or esophagoscopy evidence of atresia. Iodized oil rather than barium should be used as the contrast medium for roentgenologic studies to avoid the danger of aspiration of barium. One-half cubic centimeter given by mouth with a medicine dropper is adequate for diagnostic purposes.

The roentgenogram taken in the upright position shows the round blind end of the esophagus at the level of the tracheal bifurcation, or it may demonstrate the fistulous tract into the trachea or the absence of air below the diaphragm, depending on the type of malformation (Fig. 186).

**Treatment.** Most of the malformation can be corrected surgically. The success of operation is dependent on early diagnosis, before bronchopneumonia, dehydration and inanition have progressed to an irreversible degree. The transpleural approach rather than the extrapleural one is recommended for ligation of the fistula and anastomosis of the esophageal segments. Some surgeons perform a gastrostomy more or less routinely as a part of the procedure to permit early feeding and to avoid reflex flow of gastric secretions. When a gastrostomy is not performed, a polyethylene tube is passed through the esophagus into the stomach for the purpose of feeding. The condition of the lower segment occasionally does not permit establishing a satisfactory lumen, since its lumen may be

too contracted or too short. In such cases the cardia is ligated, a gastrostomy is performed, and the upper segment is exteriorized to avoid the otherwise inevitable aspiration pneumonia.

Adequate preoperative and postoperative management is essential for successful outcome. The operation should be deferred until the infant's condition is deemed satisfactory. The following preoperative factors are considered important: (1) preliminary broad-spectrum antibiotic therapy for the prevention or treatment of pneumonia; (2) constant drainage of the upper esophageal pouch through an indwelling catheter, the tip of which should be maintained just above the lower end of the pouch; (3) maintenance of the infant in an upright position to avoid reflux of gastric juice into the trachea and lungs; (4) parenteral administration of water and calories, preferably by slow, continuous intravenous drip of 5 to 10 per cent glucose solution in water (no saline solution is required during the first two or three days); (5) strict isolation technique (an Isolette is ideal and also permits maintenance of an increased oxygen concentration when necessary); (6) constant nursing supervision and care. Immediately before operation a cannula

FIG. 187. Tracheo-esophageal fistula without esophageal atresia. The infant was born prematurely; birth weight was 3 pounds 14 ounces. Respiratory distress appeared soon after birth and was progressive; it was accentuated when liquids were swallowed. The possibility of esophageal atresia was eliminated by passing a catheter into the stomach. The large fistula was demonstrated after the tip of the catheter had been positioned in the upper esophagus and contrast material introduced through it. There is slight narrowing of the esophagus at the site of the fistula.

should be placed in a vein for administration of blood during the operation and of water, electrolytes and calories for a day or two postoperatively. Bronchoscopic aspiration may be required preoperatively or postoperatively if atelectasis persists. Right upper lobe atelectasis is a common associated finding.

Postoperatively, the infant should be placed in an oxygen tent or enclosed incubator. Feedings through the gastrostomy tube or through the esophageal-passed polyethylene tube may be started in two or three days. The first two or three feedings should consist of 0.5 per cent physiologic saline solution and then of 5 per cent glucose solutions. If these solutions are tolerated, a milk formula of gradually increasing strength may be given. Oral feedings are usually tolerated eight to ten days after the operation. Prophylactic antibiotic therapy should be continued for five to six days postoperatively.

Stenosis at the operative site is not uncommon. At times the diagnosis is delayed because the diet is entirely liquid. Fluoroscopic studies of the esophagus will establish the diagnosis; early esophageal dilatations of the soft stenosis at the point of anastomosis are more successful in maintaining a satisfactory lumen than later dilatations of fibrous scars.

### SHORT ESOPHAGUS

This anomaly consists of a short esophagus with a portion of the stomach displaced upward through the diaphragm into the thoracic cavity. Occasionally, temporary obstruction by a foreign body leads to a roentgenologic study which reveals a stricture in the mid-thorax. This stricture is at the cardia in the midthorax with the short esophagus above it and true gastric mucosa with rugae below. These rugae can be followed through the diaphragm as a continuation of the rugae of the subdiaphragmatic stomach. The fact that the cardia becomes stenotic accounts for the symptoms. A partial thoracic stomach is more frequent than is generally supposed, and though it is a frequent cause of vomiting, there is often no stricture. It has been suggested that the stricture may be the result of reflux of gastric contents due to an incompetence of the gastroesophageal mechanism as described under *Chalasia*. The clinical picture is characterized by dysphagia, regurgitation, malnutrition and frequent attacks of complete obstruction of the esophagus.

**Treatment.** When there is no evidence of stricture, treatment consists in propping the

infant in an erect position after feeding, as described for *chalasia*. When there is stenosis, repeated dilatations are indicated, the lesion is peculiarly resistant to therapy, and occasionally one must resort to gastrostomy and retrograde dilatation. Ulcers in the supra-diaphragmatic stomach should be treated in a manner similar to other gastric ulcers.

### STENOSIS

Congenital stenosis of the esophagus without fistula formation can be found at any point along the esophageal lumen as either a web or a long segment of esophagus with only a threadlike lumen. The *symptoms* are those of esophageal obstruction, usually first apparent when the infant begins to eat semi-solid or solid food. *Diagnosis* is made by roentgenologic and esophagoscopy examinations. The *treatment* is esophagoscopy dilatation. These strictures respond more readily than does that of a congenitally short esophagus.

### EXTERNAL COMPRESSION

Obstruction of the esophagus may be caused by compression from congenital cardiac or vascular anomalies and by mediastinal tracheal or bronchial cysts. A double aortic arch (vascular ring), anomalies of the subclavian vessels and occasionally a patent ductus arteriosus may cause dysphagia. Barium fluoroscopic studies of the esophagus and recognition of both esophageal and tracheal compression by esophagoscopy and bronchoscopy assist in establishing the diagnosis. Angiocardiography is of value in questionable cases in which symptoms are severe. *Treatment* consists in surgical relief of the obstructive phenomenon.

### NEUROGENIC SWALLOWING DYSFUNCTION

Congenital anomalies of the medulla or cerebral birth injuries occasionally result in a complete lack of nervous stimulation of the muscles of deglutition. The infant is unable to swallow, and food and mucus constantly fill the pharynx and trachea. Esophagoscopy, gavage and roentgenograms show the esophageal lumen to be entirely patent. Similar symptoms occur in extreme cases of *amyotonia congenita* and *bulbar poliomyelitis*. Death usually results from aspiration pneumonia.

**Treatment.** Postural drainage and constant aspiration of mucus are necessary to prevent aspiration pneumonia. Feedings must be entirely by gavage or gastrostomy.

## CARDIO-ESOPHAGEAL RELAXATION

## (CHALASIA)

This clinical syndrome consists in vomiting following feeding when the infant is in the horizontal position. The vomiting is the result of persistent relaxation of the lower end of the esophagus. The *etiology* appears to be varied, but in most instances is not demonstrable. The course is most often limited, and for this reason chalasia has often been assumed to be the result of a temporary neuromuscular imbalance. In one instance chalasia was observed in an infant with a hemangioma at the cardia; in other instances in which vomiting has been persistent it has been associated with cerebral defects.

The vomiting begins within a few days after birth, is more or less effortless, and can usually be avoided if the infant is maintained in the erect position. Vomiting may occur during the feeding, but usually begins after the infant has been returned to the crib. In unrecognized and hence untreated cases the infant loses weight and becomes dehydrated. It may be that an occasional instance of rumination is the result of chalasia.

The *diagnosis* is established by observing the swallowing of barium under the fluoroscope. Persistent relaxation of the esophageal hiatus is observed with retrograde filling of the esophagus during inspiration or with increase of intra-abdominal pressure.

*Therapy* consists in feeding a relatively thick milk formula mixture and in maintenance of the infant in an erect (propped sitting) position for two or three hours after feedings. Permanent relief is usually obtained after a month or two of such management.

## ACQUIRED DISEASES

## ESOPHAGITIS

Acute esophagitis may complicate practically any acute infectious disease; it may be associated with inflammation of other parts of the digestive tract or may follow lacerations produced by swallowing of foreign bodies or injuries caused by ingestion of hot liquids. The lesions generally last but a few days, and the prognosis is favorable. Symptoms may be substernal pain on swallowing, dysphagia and hematemesis, or they may be entirely absent. However, some benign esophageal strictures seen in later life originate from acute esophageal ulcers associated with infectious diseases in childhood.

Chronic esophagitis is not rare in early life. It may follow an acute process or be the result of venous congestion in chronic pul-

monary or cardiac disease. Most commonly it is associated with congenital stricture or with a short esophagus.

Other infrequent causes of secondary esophagitis include diphtheria, thrush, variola, and varicella, perforation by a caseous lymph node and ulcers associated with cerebral lesions. Recognition is often impossible during life.

*Inflammatory strictures* may follow any of the conditions mentioned as esophagitis. *Symptoms* and *treatment* are those of corrosive strictures. The *diagnosis* must be established from the history and from the roentgenologic and esophagosopic appearances.

## CORROSIVE STRICTURES

The most common type of stricture of the esophagus follows ingestion of some caustic such as lye, Clorox, Drano or ammonia, or acids such as nitric or muriatic (used in soldering pastes). Even lactic acid, when given by mistake in full strength, will cause stenosis. The lesions vary from superficial pharyngitis and esophagitis to ulceration and necrosis of the esophageal or gastric wall, with a chemical mediastinitis or peritonitis which may result in death in a few hours.

**Clinical Manifestations.** When a child swallows lye, the first mouthful causes intense burning and pain, making further swallowing impossible, but the damage has already been done. The lips, chin, tongue and pharynx become edematous and covered with exudate, and similar changes occur in the esophagus. If death does not occur within the first few hours or days, the edema subsides, and swallowing may be resumed. In many instances the swallowing function returns to normal in two to four weeks. Though the ensuing period may be symptomless, it is a latent period, and a stricture usually develops within weeks or months.

Difficulty in swallowing recurs insidiously, increasing in severity over several months as strictures develop in the burned areas. At first the child has difficulty in swallowing solid food. Eating becomes slow, food is frequently regurgitated, and, later, difficulty in taking liquids becomes apparent. Often the child is considered a "feeding problem" because the accident has been forgotten and the dysphagia is so gradual in its progress. Roentgenograms then reveal strictures of the esophagus, most pronounced in the areas of anatomic narrowing: the cervical region, the cardia, and the point at which the left bronchus crosses the esophagus. Children with long-standing esophageal strictures have num-

erous evidences of nutritional deficiencies.

**Treatment.** Treatment immediately after ingestion of a caustic consists in administration of its antidote in dilute form. To administer a strong acid solution in an effort to neutralize a strong alkali adds to the injury. Olive oil applied to the denuded surface areas and administered by mouth, and analgesics administered intramuscularly are needed to relieve pain.

Gastric lavage is contraindicated because of the danger of esophageal or gastric perforation. In most instances it will be necessary to feed the child intravenously initially. A gastrostomy or jejunostomy may be necessary for continued feeding in the acute phase. A gastrostomy with the tube directed toward the cardia is most satisfactory, since this facilitates subsequent dilatation. Severe burns from ammonia or by other means occasionally cause laryngeal edema which may be obstructive enough to necessitate a tracheotomy.

The main problem in the treatment of caustic burns of the esophagus is the prevention of strictures. The Salzer technique of early management should be used in all instances of caustic esophageal burns no matter how slight the burn may appear. The technique consists in the passage of graduated shot- or mercury-filled bougies daily for two weeks, beginning twenty-four to forty-eight hours after the accident, and then gradually increasing the interval between dilatations to twice a week, once a week, once in two weeks, once a month and finally one dilatation a year for several years. Dilatations may be begun with a no. 16 French mercury-filled bougie and gradually increased to a no. 30 or 32 bougie in a small child. There is almost no danger of perforation of the esophagus by this method.

Corticosteroid therapy in conjunction with a broad-spectrum antibiotic, begun shortly after the swallowing of lye and continued for approximately ten days, has some therapeutic value in cases of severe burns. Prolonged use with high doses, however, has been associated with esophageal and gastric perforations. Further clinical investigation is needed to determine the relative efficacy of this therapy.

In the absence of early treatment, stricture formation or actual atresia may become apparent within two to four months; in some instances many years elapse before the stricture becomes severe enough to produce dysphagia. The generally accepted method of

treatment of definitely formed strictures consists in esophageal dilatations which may be guided by a swallowed string, or visually through an esophagoscope. If the stricture is extremely tight, retrograde dilations are preferred, the bougies being guided by a string advanced through a gastrostomy. When complete atresia of the esophagus follows ingestion of a caustic, endoscopic efforts at recannulization are generally successful, but occasionally external surgical procedures must be considered. Replacement of the esophagus by a section of colon or small bowel is preferred to resection of the stricture and gastroesophageal anastomosis.

#### SPASM OF THE ESOPHAGUS

Esophagospasm, including cardiospasm, may be present even in newborn infants. Esophagospasm is usually characterized by severe sudden obstruction to swallowing and reverse peristalsis and is usually initiated by emotional stress. *Cardiospasm* (achalasia, pre-ventriculosis) is the syndrome of nonorganic obstruction of the cardia associated with dilatation and hypertrophy of the esophagus. It is generally considered to be a failure of coordination of the mechanism at the cardia, preventing normal passage of food from the esophagus to the stomach. In long-standing cases there is fibrosis and disorganization of musculature of the lower end of the esophagus.

**Clinical Manifestations.** These are difficulty in swallowing, regurgitation of undigested food and fluid, cough from overflow of fluids into the larynx, especially at night, and failure to gain or loss of weight. The diagnosis is made by fluoroscopy or roentgenograms, which demonstrate the barium column in the dilated esophagus terminating in a fine point as it approaches the diaphragm.

**Treatment.** In uncomplicated cases treatment consists in dilatations of the cardia by a pneumatic bag accurately placed under fluoroscopic guidance, by a Hurst mercury bougie, by an esophagoscope or by string-guided olive-tip bougies. Psychotherapy should be considered. In advanced cases retention of food and fluids produces esophagitis, periesophageal inflammation and fibrous strictures at the cardia. Bronchiectasis may be an associated condition due to the constant overflow of food from the esophagus into the larynx and bronchi. Surgical intervention may become necessary in extreme situations; such procedures as an esophagocardial myotomy (similar to the Fredet-Ramstedt opera-

tion for pyloric stenosis) or an esophagogastrostomy may give permanent relief. Unfortunately, however, reflux esophagitis often leads to a recurrence of the symptoms and of the stricture itself, necessitating a return to dilatations or reoperation. Belladonna derivatives may be of some benefit if administered early, but are apparently of no avail in advanced cases.

### ESOPHAGEAL VARICES

Esophageal varices may occur in children with portal hypertension (Banti's disease) (p. 986) as one of the evidences of the attempt to return blood to the heart by circumventing the liver. The principal symptoms of the varices are recurrent, profuse hematemesis of bright red blood, tarry stools and systemic signs of severe hemorrhage. Careful roentgen studies with barium may outline the varices. Their presence may be confirmed by esophagoscopy examination.

**Treatment.** Treatment of portal hypertension is discussed elsewhere. Acute hemorrhage may at times be controlled by some form of tamponade. The varices may be injected with sclerosing solutions, special long needles being used through the esophagoscope. These procedures are palliative in most instances, but prolong life, reducing the number and severity of the hemorrhages.

### RETROESOPHAGEAL ABSCESS

The most frequent cause of retroesophageal abscess is extension of a retropharyngeal abscess downward to the retroesophageal component of this single, potential space; other causes are esophageal perforations, foreign bodies, spinal caries, pleuritis, pericarditis, ulceration from an intubation or tracheotomy tube, diphtheria of the pharynx or suppurating mediastinal lymph nodes. The abscess forms behind and around the esophagus and often displaces it to one side, while at the same time it compresses the more firmly seated trachea.

The symptoms are dyspnea, brassy cough, dysphagia and, as the trachea is pushed forward, swelling of the neck. Toxemia, pain, tenderness on palpation of the neck, and cervical emphysema may be present. The increased retrotracheal space can be demonstrated on lateral roentgenograms of the neck without the use of contrast medium. With its use distortion of the esophagus may be demonstrated; but if the abscess is due to esophageal perforation, barium is contraindicated.

**Prognosis.** Recovery is possible. The ab-

cess may rupture into the pleura, trachea or lung. Death may result from pressure of the abscess upon the vagus nerve or on the trachea with consequent asphyxia, or by an erosion into the great vessels of the neck with exsanguinating hemorrhage.

**Treatment.** Prompt surgical drainage is indicated. If the abscess is high, the retroesophageal space may be opened in the neck along the anterior border of the sternocleidomastoid muscle. Drainage here is effective to the level of the fourth dorsal vertebra. In retroesophageal abscesses occurring below this point a posterior mediastinotomy is generally indicated. In either instance broad-spectrum antibacterial therapy should be used. It should be recognized that such therapy could mask an advancing mediastinal infection, and only repeated lateral roentgenograms of the neck and chest will indicate the situation in the post-tracheal area.

### FOREIGN BODIES IN THE ESOPHAGUS

Infants and children swallow an unlimited variety and number of inedible objects which in most instances reach the stomach and pass through the gastrointestinal tract without complications. Occasionally they lodge in one of the three anatomically narrow points of the esophagus, from which they must be extracted.

The point of lodgment of most foreign bodies is the cervical esophagus, immediately below the cricopharyngeus muscle (Fig. 188). Here the musculature is weak in comparison with the strong muscles immediately above. The narrowing at the hiatus of the diaphragm and the cardia constitutes the second most common site for the lodgment of foreign bodies, although few lodge there. The third and infrequent site for lodgment is the normal narrowing of the esophagus at the level of the arch of the aorta.

Strictures of the esophagus, congenital or acquired, are often responsible for the lodgment of foreign bodies which would pass through the normal esophagus. Open safety pins are found most frequently in infants seven to fifteen months of age, and coins, small toys, buttons, marbles and jackstones in children from three to six years.

**Clinical Manifestations.** Initial symptoms of coughing, gagging, choking and dyspnea usually occur with ingestion of an object, no matter where it lodges. If it remains in the esophagus, pain localized in the region of the thyroid cartilage, dysphagia and drooling may

FIG. 188. Foreign body (penny) in the cervical esophagus. A, Anteroposterior and, B, lateral views show the penny in the location in which 75 per cent of foreign bodies in the esophagus are found.

follow. Once a foreign body becomes fixed, there is frequently a symptomless interval until edema around the foreign body produces evidence of obstruction, or until signs of infection resulting from esophageal perforation become evident.

Laryngeal symptoms may be produced by foreign bodies in the cervical esophagus. Dyspnea resulting from compression of the trachea may be severe enough to require a tracheotomy before the foreign body can be removed. This is especially true of marbles or jackstones. Cough and hoarseness follow obstruction of the cervical esophagus because of the irritation from secretions overflowing into the larynx. Similar symptoms occur if the foreign body erodes through the party wall.

**Diagnosis.** The diagnosis of a foreign body in the esophagus is most frequently made from the history. The child, if old enough, may state that he swallowed a button or coin, or the mother may state that the child placed some object in his mouth and choked on it. A history of difficulty in swallowing or the refusal of a child to take solid or liquid food suggests an esophageal foreign body.

When the history or symptoms suggest the possibility of a foreign body, a complete search of the gastrointestinal tract as well

as of the respiratory system must be made in an effort to locate the object. Fluoroscopic examinations and roentgenograms of the cervical esophagus, with the introduction of radiopaque media, if necessary, and of the chest and the abdomen in the anteroposterior and lateral projections are indicated.

**Treatment.** Only one type of treatment of foreign bodies in the esophagus should be considered: removal under direct vision through the esophagoscope. The use of blind instrumentation with attempts to force the foreign body into the stomach or attempted extraction by means other than by direct vision is liable to lead to esophageal perforation, mediastinitis and death. Attempts to force the foreign body into the stomach with dry bread, cabbage, cotton or roughage diets are irrational and not infrequently necessitate the removal of this material as well as of the foreign body. Such procedures may also wedge the foreign body more firmly into the esophageal mucosa.

## THE GASTROINTESTINAL TRACT

### DIGESTIVE DISTURBANCES

Gastrointestinal disturbances may have their origin from lesions in the digestive system or may reflect disturbances of other systems of the body. Since such symptoms as anorexia, vomiting, diarrhea, are frequent complaints in pediatric practice, they are considered separately.

#### ANOREXIA

At all ages anorexia is an accompaniment of acute febrile diseases and is frequently present in chronic diseases. Allergy to specific foods is an occasional factor, although children may be fond of foods to which they are allergic. Long-continued undernutrition may be a result of anorexia and in turn may become a cause of it; in such instances the anorexia is difficult to overcome. Anorexia is also a symptom of specific nutritional deficiencies.

**Feeding Habits.** As a persistent symptom, anorexia arises frequently from faulty feeding habits. In the first year of life this condition results from a number of factors, including attempts at forced feeding and too frequent feeding. It is common in children in the age range of three to five years. Too great supervision of the child's eating habits may result in antagonism and detract from the pleasure of eating to such a degree that anorexia becomes persistent. The failure of parents and even of physicians to recognize that the growth rate decelerates rapidly in late infancy and early childhood is often responsible for attempts to force eating in order to maintain the rapid gain in weight of early infancy.

Failure to recognize that children's appetites may vary from meal to meal or from day to day is also frequently responsible for antagonism toward eating. Moreover, the gastric capacities of children of the same age

vary, as do their caloric needs, and parents may err in attempting to make all children conform to a single pattern. Refusal to eat, in some instances, is the child's means of attracting attention or maintaining a position of authority within the family group. Poor feeding habits of other members of the family are also frequently reflected in children. This applies not only to special food dislikes, but also to total intake.

**Nervous Excitement.** Anorexia resulting from nervous excitement or tension is as frequent among children as among adults. When this condition is persistent, the term "anorexia nervosa" (see p. 89) is used to describe it. It is important to recognize that temporary aversion to food is common to practically all children during periods of great excitement or emotional stress and varies only in degree. Emotionally unstable children frequently reflect behavior patterns of their parents, and in other instances emotional disturbances are accentuated and prolonged by the interference of adults. Tension at mealtimes between other members of the family or tense situations which directly involve the child are frequent causes of poor eating habits. In older children worries and anxieties which have their origin outside the home must be considered in the evaluation of persistently poor eating habits. Insufficient time for meals, fatigue resulting from too great activity or too little rest, and unattractive meals are other factors which must be considered.

#### VOMITING

Vomiting is such a common symptom in children that it often excites little concern. The "spitting up" or regurgitation by infants after feeding, or the occasional vomiting of infants and children, may not have serious conse-

quence, but persistent vomiting has. Not only may it reflect some serious underlying disturbance, but also it may be responsible for sufficient loss of body fluids and electrolytes to produce dehydration and alkalosis. Failure to retain food may be responsible for the ketosis of starvation. In all instances an attempt should be made to understand the cause of vomiting so that proper remedial measures may be instituted.

**Vomiting by the Newborn Infant** (pp. 330, 665). If vomiting is persistent, one should think especially of congenital obstructive anomalies of the alimentary canal, irritation of the stomach from swallowed amniotic contents, and intracranial birth injuries.

**Faulty Feeding of Infants.** Vomiting resulting from improper feeding techniques or improper diets is discussed on page 130. The vomiting of overfeeding usually occurs shortly after feeding, as does that of failure to eruct swallowed air. This type of vomiting is more properly termed "regurgitation" and is principally a nuisance. Other factors which must be considered in regurgitation are too tight clothing, especially about the abdomen, and the placement of the infant on his back or left side immediately after feeding instead of on his abdomen or right side.

**Acute Infectious Diseases.** Vomiting is a common initial symptom.

**Acute Gastric Indigestion.** This type of vomiting is frequent among children. It results from overeating, especially of foods whose digestion is naturally prolonged, and from eating during nervous excitement.

**Acute Gastrointestinal Diseases.** These diseases include the various diarrheal disturbances. Vomiting is a serious symptom, owing to the additional loss of water and electrolytes and because oral administration of fluids is not possible.

**Pyloric Obstruction.** Vomiting from this cause has a characteristic pattern (p. 658).

**Intestinal Obstruction** (p. 665). The vomiting of intestinal obstruction is persistent. Unless the obstruction is relieved, the vomitus contains intestinal contents, the nature depending upon the level of the obstruction.

**Acute Peritonitis.** In contrast to chronic peritonitis, vomiting is practically a constant accompaniment of acute peritonitis and in the late stage is due to paralytic ileus.

**Appendicitis.** Vomiting is an early symptom in acute appendicitis; it becomes manifest again when the appendix ruptures. It is

greater with generalized peritonitis than with a localized abscess.

**Organic Nervous Disease.** Vomiting is an early symptom of acute meningeal disturbances and may be persistent when the infection is not controlled. Space-taking intracranial lesions such as neoplasms, abscesses and hemorrhages frequently are responsible for vomiting, which characteristically is projectile in type, aggravated by change in position as in arising in the morning and unassociated with nausea. It may, however, be nonprojectile and associated with nausea.

**Toxic Vomiting.** This is an unsatisfactory designation, which is used for vomiting from such causes as uremia, diabetic acidosis and certain poisons, such as apomorphine, tartar emetic and digitalis, which presumably stimulate the vomiting center. The vomiting that often occurs in the initial stages of acute infectious diseases and in the late stages of diphtheria and typhoid fever is also probably of this order. A similar mechanism may explain the vomiting.

**Reflex Vomiting.** Vomiting may be initiated by conditions which stimulate the gag reflex, such as a copious postnasal drip, enlargement of the uvula, persistent or spasmodic cough such as that of pertussis, and gagging on food. This last is common in infants who have been started too early on solid food or whose introduction to it has been too long delayed. Some children have exceptionally sensitive gag reflexes, and vomiting may be induced by slight provocation.

**Nervous or Habit Vomiting.** Nervous or habit vomiting is seen in neurotic children and is excited by emotional disturbances of all sorts. Carsickness, seasickness and the vomiting following swinging may in many instances be placed in this category, although the possibility of a relationship to visual and aural disturbances must not be disregarded.

**Other Causes of Vomiting.** Gastrointestinal allergy, anesthesia, especially that induced by ether, operative manipulation of the abdominal organs, the swallowing of caustic poisons (esophageal stricture) and adrenal insufficiency in early infancy may all be causes of vomiting.

When vomiting occurs before breakfast and is associated with nausea and a sense of faintness, the possibility of *hypoglycemia* should be considered.

**Treatment of Vomiting.** Vomiting should in all instances be considered a symptom, and principal attention should be directed to

determination and then correction of the cause. When considerable amounts of water and electrolytes have been lost and there is ketosis, parenteral fluid therapy (p. 186) may be necessary. Occasionally, when vomiting is persistent, an attempt to control it by drug therapy may be justified. At present, principal interest in this respect is centered in the phenothiazine group of drugs, such as chlorpromazine (Thorazine, p. 226), promazine (Sparine) and promethazine (Phenergan, p. 223), all of which can be given in rectal suppositories.

## RUMINATION

### (MERYCISMUS)

**Etiology.** Infants occasionally expel gastric contents by a series of movements analogous to those made in rumination by cattle. Rumination usually occurs in young infants, but is rare at any age. The cause is not understood; perhaps in most instances it is due to a disturbed parent-infant relationship, and particularly to a lack of affectionate care.

**Clinical Manifestations.** The symptoms are repeated regurgitations of small amounts of food, which usually begin a half-hour or so after feeding. Rumination may be observed after all or only some of the feedings. Some of the regurgitated food may be promptly swallowed again, some may be lost from the mouth, and some may be held in the mouth or pharynx for a time. The return of food from the stomach is preceded by peculiar but characteristic chewing movements, with the tongue pushed forward within the oral cavity. Sometimes the infant starts the procedure by putting his fingers or other objects into his mouth. Both breast-fed and artificially fed infants are affected, and the kind of food seems to have little influence, although some infants will retain solid food, such as thick cereal, but ruminate liquids.

**Diagnosis and Prognosis.** The diagnosis is usually obvious from the nature of the act, and rumination is not likely to be confused with cardiospasm, pylorospasm, esophageal stricture or achalasia, although such conditions might be associated with it. The prognosis depends on the severity of the condition and on the possibility of establishing satisfactory environmental conditions for the infant. Death has occurred from extreme emaciation.

**Treatment.** Many therapeutic techniques have been used, but one may doubt whether any of them have been really successful.

These have included the use of thickened feedings and restraining devices such as a tightly fitting cap with a strap which passes under the jaw and prohibits opening of the mouth. The suggestion of Richmond to provide psychotherapy for the mother and an abundance of affectionate care for the infant would seem to be much more appropriate.

## RECURRENT VOMITING

### (CYCLIC, PERIODIC OR ACETONEMIC VOMITING)

**Etiology.** This condition, characterized by irregularly recurring attacks of vomiting of several days' duration associated with ketosis, is a syndrome and not a disease entity. There is no adequate explanation for the attacks, although they seem to be more frequent in emotionally unstable children than in phlegmatic ones. The incidence is higher in private than in clinic practice, with a relatively large percentage of the cases among the so-called intelligentsia. There is frequently a family history of migraine. Attacks usually begin early in childhood, rarely in infancy, and recur at intervals ranging from a month or two to two or three attacks a year. There is often some initiating factor such as fatigue, emotional excitement or onset of an acute infection, but at times there is no apparent "trigger mechanism." Millichap suggests that cyclic vomiting may be a form of epilepsy.

There is no evidence that these children have any inability to burn sugar. The greater readiness in all children in comparison with adults to develop ketosis during periods of glycogen depletion explains the rapidity with which ketosis develops with persistent vomiting. The fact that the vomiting can usually be controlled by sedation favors a neurogenic basis rather than a metabolic defect.

**Clinical Manifestations.** The onset of an attack may be sudden, with vomiting from the first, or there may be a prodromal period of hours or a day during which there is malaise, irritability, anorexia, abdominal discomfort, coated tongue, and constipation. The initial vomitus consists of ingested food, but it soon becomes mucoid, then bile-stained, and often blood-stained or brownish. Vomiting is often forceful, with much retching, and occurs whenever anything is swallowed and even when no food or liquid is taken. There is little or no fever unless the attack has been initiated by an acute infection. Thirst is great, headache and abdominal pain are frequent, and obstinate constipation is the rule.

The abdomen is usually retracted, rarely distended, and at times there is tenderness. As the attack continues, prostration may become extreme, there is an anxious expression of the face, the eyes are sunken, there is an odor of acetone on the breath, and the urine, which is scanty, contains ketones and often albumin. Hemoconcentration may be responsible for an apparent increase in nonprotein nitrogenous constituents.

**Diagnosis.** Diagnosis is based on a history of previous attacks and the onset of persistent vomiting without apparent cause. The vomiting may be responsible for an alkalosis, but in protracted cases this may be counterbalanced by the ketosis and by retention of other acid metabolites, when hemoconcentration is sufficient to be responsible for a decrease in renal function. Appendicitis, intestinal obstruction and other organic causes of vomiting must be eliminated in the differential diagnosis. Occasionally a child with recurrent spontaneous hypoglycemia may be incorrectly thought to have recurrent vomiting.

Every effort should be made to determine the underlying cause or "trigger mechanism" for the individual attacks; the child should have an electroencephalogram to test the possibility of epilepsy as the etiologic factor. There should also be a psychologic evaluation of the child and his family.

**Prognosis.** In spite of the extreme prostration frequently present, the convalescent period is short. As a rule, attacks become less frequent during the latter part of childhood and disappear at or before puberty. Migraine may be a sequel during later life.

**Treatment.** Treatment is directed toward control of the vomiting and correction of the ketosis. Food and liquid by mouth should be discontinued in severe cases, and only cracked ice given to alleviate the dryness of the mouth. In milder cases, sips of glucose water or ginger ale may be permitted if they do not increase the vomiting. The two most important measures are parenteral administration of glucose and saline solution, and sedation. The vomiting can be controlled in the majority of instances by hypodermic injection of sodium phenobarbital. Chlorpromazine or one of the other phenothiazines might also be administered in a rectal suppository. Neither should be administered until the possibility of a surgical lesion has been eliminated.

Specific physical defects should be corrected, the nutritional status should be im-

proved, and, when necessary, psychiatric treatment should be provided.

### EPIDEMIC NAUSEA AND VOMITING

**Etiology.** The occurrence of mild respiratory infection in association with nausea, vomiting and, at times, diarrhea in epidemic outbreaks has suggested to some that this clinical pattern may represent a disease entity. The infection is presumed to be a viral one, but it would be surprising should there prove to be a single etiologic viral agent. Varying degrees of gastrointestinal symptoms are not uncommon in epidemic viral infections of the upper respiratory tract. Such manifestations are as a rule more common and more pronounced in infants and children than in adults.

**Clinical Manifestations.** Vomiting is a more constant symptom among children than among adults, who often complain only of severe nausea. The onset is abrupt, and the vomiting is often projectile. The urgency may be so great that a child who has been otherwise well is unable to leave the room before vomiting occurs. Nausea is usually a consistent manifestation. There is often a sense of dizziness, and even a feeling of faintness. Frontal headache and abdominal discomfort are common symptoms. Diarrhea is not invariably present and is usually a minor manifestation.

There is usually slight fever, the pharynx is moderately infected, and the tongue is usually coated and its papillae enlarged.

**Treatment.** Treatment is symptomatic and consists in mild sedation and the avoidance of food other than liquids until the vomiting is controlled. The phenothiazines may be effective in these cases.

### NORMAL AND ABNORMAL STOOLS

The pediatrician should be familiar with the characteristics of the normal stools of infants and children as well as of the various types of abnormal stools. Though the information gleaned from examination of the stools has limitations, it may contribute to a better understanding of a particular disturbance.

**Normal Stools.** The characteristics of the meconium stools of the first few days of life and of the transitional stools are described on page 290. When breast-milk feeding is well established and the infant's intake is composed entirely of it, the stools are yellow to golden, of salvelike consistency and faintly acid in reaction.

When cow's milk is ingested, the stools tend to be paler yellow, or they may assume more of a brownish color, are firmer in consistency, less acid in reaction and may even be slightly alkaline; there is a more decided odor, owing to decomposition of protein. A ratio of 3:1 between the fat and protein produces an acid stool, whereas a ratio of 1:1 causes the stool to become alkaline. The pH of the stools of normal breast-fed infants varies from 4.7 to 5.1, greater acidity being encountered as a rule only in diarrheal conditions. Infants fed on protein milk, cow's milk formulas or whole acid milk with carbohydrate added generally have stools which approach a pH of 7 or higher. Oral administration of acids or alkalis has little effect on the reaction of the stools.

The number of stools varies considerably, breast-fed infants tending to have more frequent movements than artificially fed ones. Breast-fed infants average from two to four stools a day during the first three or four months of life, whereas artificially fed infants average about only one or two stools. By the end of the first year of life the majority of infants have only one stool a day, although more or less than one is not incompatible with a normal regimen. The character of the stool is more important than the number in the estimation of whether the infant has diarrhea or constipation.

A normal stool contains approximately 80 per cent water. The greater part of the residue consists of cellular elements, mucus and bacteria. Fat is present in the form of neutral fat, fatty acids and soaps. The fat is largely a residue from unabsorbed foods; some comes from bile, bacteria and cellular detritus, and some from lipids excreted from the blood through the intestinal wall. The fat content of infants' stools varies tremendously and may be as much as 35 per cent of the weight of the dried stool of artificially fed infants and as much as 50 per cent in breast-fed infants. The sugar of the infant's diet is entirely absorbed. Starch is not completely digested and may be demonstrated in the stool by the iodine test. Only about 8 per cent of the protein ingested is lost in normal stools. The greater part of the nitrogen and phosphorus recoverable from the stools of breast-fed infants is derived from the digestive secretions and not from the milk. From 8 to 10 per cent of the dried stool consists of mineral matter, chiefly calcium, which is partly derived from food and partly secreted into the intestine from the blood.

Curds may be found in the stools of both breast-fed and artificially fed infants and in small number are of no particular significance. They are whitish, but the outer coating is yellow or brown; they are composed of a casein coagulum; those of breast milk stools are much smaller and less firm in consistency than those of cow's milk. The small white curds which appear in diarrheal stools represent undigested neutral fat.

Various ferments are present in the stools, such as diastase, lactase, invertin, trypsin, rennin and a fat-splitting ferment.

Microscopically, the stools of an infant exhibit fat globules of various sizes, needles of fatty acids, innumerable bacteria, cholesterolin plates, epithelial cells, small round cells, calcium salts in crystalline form, granular detritus, and occasionally bilirubin crystals, yeast fungi and protein matter.

As the infant grows older the stools become a darker yellow, and, when the diet is more varied and especially when the amount of milk is relatively diminished, they acquire more of the characteristics of the stools of adults in both color and odor. By the time the child is about two years of age stools become formed, although even young infants may pass fully formed stools, especially when they are ingesting a diet with a high protein content.

**Mucous Stools.** Mucus is often present in the stools of infants and in small amounts may have no significance. During starvation the stools consist of thin mucoid secretions of the intestine which are stained a brownish tint (*starvation stool*). Mucus is generally present in considerable quantity after administration of a purgative such as castor oil. In older children it may represent a functional disturbance and be associated with emotional or neurotic disturbances. It is present in large quantity in inflammatory conditions. Stools composed almost entirely of blood-stained mucus occur in dysenteric conditions and in intussusception. Undigested starch may resemble mucus in appearance, but can be distinguished by the iodine reaction.

**Protein Stools.** The odor of putrefaction may be present in the stools of infants who ingest large amounts of protein or whose digestion of protein is impaired. The color is brownish-yellow or sometimes a greenish-black, and mucus may be present. Tough, yellowish, beanlike protein curds are often present after ingestion of unboiled milk.

**Fat Stools. Soap stool.** This depends upon an excess of fatty acids combined with cal-

cium or magnesium to form a soap. The stool is white or gray, shiny, fairly firm, homogeneous, crumbly or salvelike and of acid reaction, and has a rancid or sour odor.

**Fatty stool.** The stool is yellow to gray and soft and bulky, has a greasy appearance, and will produce a grease spot when placed upon paper. If protein is also present in large amount, the odor is cheesy and offensive; when there is also undigested carbohydrate, the stool is frothy. Such stools are seen in the celiac disturbances.

**Curdy stool.** Fat curds occur most often in loose or diarrheal stools, and the stool has an acid reaction. The curds are generally small and white. (See also Normal and Protein Stools.)

**Carbohydrate Stools.** Stools from diets exceptionally high in carbohydrate content are of normal consistency, smooth, brown or yellowish-brown, and have an acid reaction. Starch present in excess may be demonstrated by the iodine test. When there is indigestion of carbohydrate and decomposition of it in the intestinal tract, the stools become thin, frothy, light yellow or often green, the odor is suggestive of acetic acid, and there is an acid reaction.

**Green Stools.** A faint pea-green color when the stool is passed or developing shortly thereafter is not abnormal; it results from oxidation of bilirubin (responsible for the yellow color) to biliverdin. Green watery stools are common in diarrhea.

**Blood in the Stools.** Occult blood in the stools of newborn infants who have no other evidences of hemorrhage is not uncommon and may be of no particular significance. Gross evidence of fresh or digested blood, however, requires explanation. Streaks of fresh blood in the stool may result from bleeding hemorrhoids, anal fissures, rectal polyps or the passage of a large hard stool. Blood in combination with large amounts of mucus occurs in intussusception and, with mucus and pus, in colitis. Among the acute infectious diarrheal conditions, blood is especially likely to be present in amebic or bacillary dysentery. When there is extensive bleeding in the stomach or high in the intestinal tract, or when large amounts of blood have been swallowed, the stools are reddish-black. Under these circumstances the various blood dyscrasias and ulceration of the stomach or duodenum should be considered in the differential diagnosis. Ingested iron causes the stools to become black, and bismuth causes them to be greenish-black. When the blood

in the stool is midway between that of the fresh state and that characteristic of bleeding high in the stomach or duodenum, the possibility of a Meckel's diverticulitis, intestinal polyps and the blood dyscrasias should be considered.

## CONSTIPATION

The term "constipation" indicates that intestinal evacuations are too infrequent, too small in amount or too firm and dry. There are, however, individual variations in frequency which must be considered within the normal range. Some infants, for example, of an age when two or three stools usually occur daily may not average a stool a day, but they are not to be considered constipated if the evacuation is of sufficient size and is normal. In older children, in whom but one movement daily is to be expected, there may be two or three, but they may be hard and small, and the child is actually constipated. There is, in fact, no absolute rule for the number of evacuations which should occur daily, nor is it necessary that there be a stool every day. The quality of the stool is a better measure of constipation than is the frequency of evacuation. The causes of constipation are shown in Table 87.

**Clinical Manifestations.** The symptoms accompanying constipation depend mainly upon its cause. In chronic constipation general symptoms may be entirely lacking, and the child may appear to be in good health. There may be abdominal discomfort, flatulence and anorexia, and, infrequently, fever, malaise and vomiting. Such nervous symptoms as headache and disturbed sleep are rare. Apparently some of the nervous manifestations which occur in constipation are reflex and are caused by mechanical distention of the lower bowel; they can hardly be due to absorption of toxic substances, as is sometimes claimed, since they almost immediately disappear when the rectum is evacuated. Local disturbances, such as fissures, rectal prolapse or hemorrhoids, may at times be the cause of or may be secondary to constipation. The retained fecal masses at times may be palpated as hard nodules through the abdominal wall, occasionally attaining tumor-like size and hardness.

**Diagnosis.** The decision whether an infant or child actually has constipation should be determined from a description or preferably from an examination of the stool. Small ribbon stools or small inspissated, ball-shaped

fecal masses are likely to be associated with a spastic or irritable colon; hard, dry, small stools with atony of the gut or improper dietary habits; and normal stools with anal or rectal stenosis in infants.

In every instance a visual and digital examination of the anus should be made. Anal stenosis in infants is not rare and should be considered in the differential diagnosis of every constipated infant. When the anus of an infant does not admit the examiner's little finger easily, the diagnosis is established (p. 680). Proctoscopic and roentgenologic examinations are rarely necessary, but should be made when the cause is not apparent from an evaluation of the history and from examination of the stool, anus and rectum (digital examination). Roentgenologic examination is an important aid in the diagnosis of spastic colitis, a rare condition in children.

**Treatment.** It should be proved that constipation actually exists before treatment is instituted.

**Acute constipation.** A simple enema may be all that is necessary in acute constipation. If the feces are hard or if there is impaction, 2 to 4 ounces (60 to 120 cc.) of mineral oil may first be injected and allowed to remain for a few hours. When indigestion accompanies the constipation, a cathartic such as milk of magnesia in infants and citrate of magnesia in older children may be prescribed.

**Chronic constipation. DIET.** In the treatment of chronic constipation attention should be given to the cause, which is usually a faulty diet or faulty bowel habits. It should be remembered that a high or even average casein content of a milk mixture tends to produce hard, firm stools. An increase in the quantity of sugar in the formula of infants or a change in the type of sugar may at times be helpful. In some instances the use of oatmeal water as a diluent is of benefit. The quantity of fat in the diet should not be increased beyond the usual requirement. The quantity of milk should be diminished if it has been excessive and that of solid food increased; water should be given freely. Butter-milk and acidophilus milk may sometimes be used with advantage instead of plain milk.

Fruit juices and, later, fruits themselves are excellent, especially prune pulp and applesauce. For older children, figs, prunes, apricots and dates in moderate quantities are likely to be helpful. Such green vegetables as spinach, beet tops, lettuce, asparagus tips and string beans, and such flours as oatmeal,

whole wheat and graham should be included in the diet. Bran biscuits or crumbled bran is frequently of value. Broth may exert a laxative action through the salts contained in it. In general, foods which are largely digested and absorbed, such as the protein of milk and foods consisting chiefly of starch, should be restricted in amount; those containing considerable residue, such as green vegetables, many of the fruits, and the outer coating of grain, should be increased.

**TRAINING.** This is of great importance; too early training and coercive methods should be avoided (p. 136). Older children should attempt to establish a time for defecation when the inclination is most strongly felt and there is nothing to cause hurry. Shortly after eating is generally a suitable time, since ingestion of food increases intestinal peristalsis. Though straining is not to be encouraged, a sufficient time (fifteen minutes or so during the period of habit formation) allowed on the toilet will often be followed by a stool, even though at first

Table 87. Causes of Constipation

<i>Insufficient or Improper Food</i>
In both breast-fed and bottle-fed infants there may be a deficiency of food in total quantity, and in artificially fed ones of an ingredient such as carbohydrate or fat. High protein mixtures tend to cause hard, firm stools, and high fat mixtures may cause dry soapy stools. There may be too much milk and too little residue from other foods. Boiling the milk has little effect in producing constipation
<i>Spasticity of Intestine</i>
Irritation by cathartics or too much residue; spasm of rectal sphincter from fissure or hemorrhoids
<i>Lack of Muscular Tone</i>
Lack of tone of intestinal and abdominal muscles may occur in malnutrition, rickets, anemia, any protracted illness, lack of exercise, and after continued use of laxatives, enemas and suppositories
<i>Anatomic Abnormalities</i>
Unduly long or tortuous sigmoid; megacolon; various forms of intestinal obstruction; enteroptosis; anal stenosis
<i>Faulty Habit</i>
Irregular habits of evacuation; injudicious use of suppositories, enemas and laxatives

no inclination is felt. Prolonged periods on the toilet should be avoided. A low seat may help when evacuation is difficult with a higher one.

**LOCAL ANAL MEASURES.** Stretching of the anal sphincter is occasionally serviceable for spasm of the muscle or stenosis. The mother should be instructed to perform daily dilatation, wearing a lubricated finger cot. The finger should remain in the anus for five minutes or so. For anal fissures see page 682.

**SUPPOSITORY AND ENEMA.** These should be used only as temporary measures. Suppositories may be made of soap, glycerin and soap or gluten. Sometimes the introduction of an oiled thermometer gives all the local stimulus that an infant requires. Suppositories may be used for several days in training to a daily habit, but no longer. Small enemas are useful in emptying the bowel in chronic constipation, but should not be used as a routine measure.

**DRUG THERAPY.** Drugs should be avoided so far as possible. In infancy milk of magnesia (2 to 8 cc.) added to the bottle may be helpful. Dioctyl sodium sulfosuccinate (p. 216) has proved to be effective. The use of any drug should be eliminated by gradually decreasing doses as improvement in bowel habit is attained from dietary and regulatory measures. Liquid petrolatum absorbs vitamin A, and vitamin A should be abundantly supplied if this substance is used.

**Spastic constipation.** This is rare in children and requires special consideration. Laxatives and purgatives should be discontinued, and a lubricant or dioctyl sodium sulfosuccinate (p. 216) substituted until satisfactory bowel habits are established. Roughage in the diet should be avoided. Tincture of belladonna, atropine or Syntropan in conjunction, when necessary, with phenobarbital for its sedative effect, constitute the medicinal therapy. Most important is correction of the underlying psychologic difficulties. Every effort should be made to establish normal bowel habits without dietary restrictions and without medicinal therapy.

### ENCOPRESIS

Encopresis, or fecal incontinence unassociated with organic lesion or disease, is not a rarity in pediatric practice. It occurs most often in the postinfancy and preschool years, but may persist into later childhood. Most often it takes the form of frequent fecal soiling, with severe constipation; less often there are intermittent larger evacuations. Encopresis may be considered to exist when children beyond three years of age do not have bowel control and have no organic explanation for the incontinence. Enuresis is frequently associated. The principal causes are mental retardation and emotional disturbances.

Many of the children with average intelli-

Table 88. Differentiating Features of Psychogenic and Aganglionic Megacolon

Psychogenic Megacolon	Aganglionic Megacolon (Neurogenic)
Admitting complaint: Fecal soiling	Admitting complaint: Constipation without fecal soiling
Age at onset: 2nd year or later	Age at onset: Birth or first weeks of life
History: Coercive bowel training Toilet training successful at some time or always unsuccessful Infrequent use of toilet after onset Defecation in standing or supine position Inhibition of stool Colicky abdominal pain Periodic voluminous stools	History: Lack of coercive bowel training (enemas only for true constipation) Toilet training usually successful Use of toilet for defecation Defecation in sitting position Rarely abdominal pain Pellet-like or ribbon-like stools
Past history: No episodes of intestinal obstruction	Past history: Frequent episodes of intestinal obstruction
Physical examination: Feces-packed rectum	Physical examination: Empty rectum
Fluoroscopy (Neuhauser's technique): Absence of spastic segment of rectum or rectosigmoid	Fluoroscopy (Neuhauser's technique): Presence of spastic segment of rectum or rectosigmoid
Course: Negligible mortality	Course: High mortality if untreated

Adapted from Garrard and Richmond: Pediatrics, Vol. 10.

gence who have encopresis have been toilet-trained at least for defecation. Any type of emotional disturbance may be the underlying factor for the development of encopresis. In many instances these children have had early, coercive toilet training and a distinct lack of parental affection. The parents often make a fetish of daily bowel movements, and the use of enemas, suppositories and laxatives is common. Some time later, perhaps with any of a variety of emotional "trigger mechanisms," the child refuses to use the toilet, and obstipation and then encopresis follow. In some instances the clinical pattern may be that of megacolon (see Table 88 and p. 673). Treatment is psychiatric for both parents and child.

## DIARRHEAL DISORDERS

### DIARRHEA IN INFANTS AND CHILDREN

Diarrhea is a major clinical manifestation of a variety of disorders which collectively constitute one of the principal causes of illness and of mortality among infants and children throughout the world. The problem is a much more serious one during infancy than in later childhood. This difference is due in part to the infant's greater susceptibility to infection and to his lesser ability to combat it, but mainly it is due to the relatively greater disruption of the water and electrolyte balances within the infant than in the older child. Although infection itself may be the cause of death, more often death can be attributed to the effects of dehydration and acid-base imbalance, usually acidosis.

Among people of high socio-economic standards the decrease in the incidence of diarrhea has been tremendous and has been principally responsible for the great decrease in infant mortality rates since 1900. In countries in which standards of living continue at a low level among a large portion of the population, infant deaths from diarrheal disorders continue at a high rate. This difference is due almost entirely to the effective use of methods for the preparation, sterilization and storage of milk or formulas and the handling of other foods for infant feeding so that bacterial contamination is avoided. Such diarrheal disorders have been termed "filth diarrhea" and occur mainly in hot, humid climates, where bacteria can grow luxuriantly in milk or other foods intended for infant feeding.

In most areas in the United States the distinct seasonal variation in the incidence of diarrhea among infants has largely disap-

peared, and the incidence in the winter months now approximates that of the summer ones.

**Etiology.** In the majority of instances the etiologic agent of acute diarrheal disturbances is not determined. From an epidemiologic standpoint the diarrheal problem among infants and children can be approached on the basis of age groups: the newborn period, infancy and childhood.

Any of the known intestinal pathogens can presumably infect a person of any age, but there are differences in susceptibility at various ages and, as noted, differences in the clinical patterns. The clinical disturbances of the recognized enteral infectious diseases in which diarrhea is a significant manifestation are described elsewhere. These are bacillary dysentery, amebiasis, typhoid fever, salmonella infections and food poisoning. Diarrheal disorders in the newborn infant are discussed on pages 344 and 346.

*Diarrhea in the newborn* presents its biggest problem as an epidemic in the nursery (p. 346). Most of the intestinal pathogens have either been incriminated or suspected in individual epidemics. In addition, for a number of organisms which are commonly found in the intestinal tract during health, there is presumptive evidence that they may act as pathogens under certain circumstances, and presumably more often in early infancy than later. These include the paracolon, *Proteus*, *Pseudomonas*, staphylococcal and streptococcal groups in particular. In the 1940's rather strong presumptive evidence was presented in support of viral agents as the principal etiologic factor in the epidemic form of diarrheal disease in the newborn (Hodes and Light, and Buddingh and Dodd). Subsequently attention has been directed to pathogenic strains of *Escherichia coli* which are identified by agglutination. A number of strains or serotypes have now been identified as unquestioned pathogens (p. 344). Although these strains may presumably cause diarrheal disorders at any age, it would appear that they are more likely to cause intestinal disease in the first year or so of life, especially in the newborn period, when perhaps they may be the most frequent cause of nursery epidemics. Likewise they appear to be a common cause of nosocomial infections on infant wards. Epidemiologic studies are now under way which it may be hoped will clarify the situation. It would be a mistake, however, at this time to oversimplify the problem, and it must be assumed that a number of viral

and bacteriologic pathogens can cause diarrheal disease in the infant. As an example, recent evidence incriminates certain strains of the ECHO viruses (p. 531).

The problem in *infants* subsequent to the newborn period varies greatly in different socio-economic groups. In those of the lowest order contamination of milk formulas and other foods is still the most important source of infection. In the higher socio-economic groups infections of this sort are now comparatively rare, and most infections would seem to be transmitted by infected persons or "carriers." Perhaps the most frequent causes at present are the pathogenic serotypes of *E. coli* mentioned above and various viral agents. In addition to enteric viruses, it is possible that some of the respiratory viruses may be responsible for mild diarrheal disturbances in conjunction with the respiratory infection. It is not uncommon to observe diarrhea in an infant of a family of which older members have an epidemic respiratory infection.

In *childhood*, diarrheal disturbances become much less frequent and relatively less severe. Many of the mild diarrheal disorders would seem to be due simply to overeating and perhaps in some instances to a combination of this with nervous excitement and exhaustion. Emotional disturbances must always be recognized as a possible cause. It is also possible that food contamination of a slight degree which has little or no effect on adults may be responsible for mild diarrhea (food poisoning, p. 1374) in children. In all instances of severe diarrhea a careful history of possible sources of infection and bacterial cultures of the stools should be obtained.

At present it is necessary to pay special attention to the *Staphylococcus aureus* as a cause of diarrheal disease. Its association with acute food poisoning has been described (p. 1374). A similar type of clinical pattern may also result from enteric staphylococcal infections which are permitted to become established as a result of alterations in the intestinal flora during prolonged antibiotic therapy, especially with the tetracyclines. Diarrhea which is presumably due to direct enteric infection by the *Staphylococcus* in association with staphylococcal infections elsewhere in the body such as skin lesions and pneumonia is not uncommon. Such infections are seen principally in infants. In addition, primary staphylococcal enteritis has been reported as a cause of an epidemic of diarrhea in the newborn (Smith).

Antibiotic-induced diarrhea may not be as frequent in infants and children as in adults, but it does exist. In addition to staphylococcal enteritis mentioned above, other infectious agents may overgrow in the intestinal tract or be permitted colonization as a result of disruption of the usual intestinal flora by therapy with the various antibiotic agents as well as the sulfonamides. Staphylococcal and fungal (*Candida albicans*) infections would appear to be the more frequent ones, but infections with *Proteus*, *Pseudomonas* and perhaps certain other bacteria may be significant.

Parenteral infections have been accorded a high place as a cause of diarrhea, especially in infants, but it is doubtful whether they are as frequently a cause as was previously supposed. With the more universal sterilization of infants' formulas and the increasing practice of avoiding overfeeding during acute infectious diseases, intercurrent diarrheal disturbances during parenteral infections have become relatively uncommon. The majority of diarrheal disturbances attributed to parenteral infection would seem more likely to be secondary intestinal infections in infants whose natural resistance was temporarily lowered. Grippelike infections which tend to occur in epidemic form and have in their clinical patterns varying degrees of upper respiratory tract infection and of diarrhea are not considered parenteral infections.

A number of noninfectious conditions may be responsible for diarrheal disorders. These include allergy to certain foods (p. 1326); metabolic disorders such as those associated with hyperthyroidism, uremia and acidosis; emotional excitement and fatigue; direct irritation of the intestinal tract by such food-stuffs as unripe fruits or vegetables, or those which contain large proportions of undigestible material or have an especially high fat content. Excessive ingestion of ordinary foods, especially by infants, may also be a factor. The persistent or injudicious use of laxatives and purgatives is also a cause. So-called starvation diarrhea, in which the stools contain an excessive amount of mucus and a little fecal material, is not, strictly speaking, a diarrheal disturbance. Diarrhea may be a prominent symptom of congenital aganglionic megacolon in early infancy.

**Clinical Manifestations.** See page 346 for description of diarrhea in the newborn; for clinical manifestations in older children, see descriptions under bacillary dysentery, salmonella infections, amebiasis and food poison-

ing. The descriptions here apply principally to infants and very young children.

**Mild diarrheal disturbances.** Occasionally there are such prodromal symptoms as slight fever, some irritability and a disinclination to eat. Severe vomiting is not a common symptom. The frequency of stools varies; there may be only two or three a day or as many as ten or twelve. Temporary reduction in oral feeding usually results in abatement of the diarrhea, and there is little or no evidence of dehydration.

**Severe diarrheal disturbances.** The severe cases vary widely; in general they can be placed in two groups: (1) cases in which the onset is only moderately severe and toxic manifestations are greatly accentuated when dehydration and electrolytic disturbances have become a factor; (2) cases in which the onset is abrupt with high fever and extreme toxicity.

In the first group there may or may not be fever. There is often vomiting at the onset, but it is usually not persistent. It may return in the later stages if dehydration and acidosis develop. Diarrhea appears within twenty-four hours of the onset; the stools are at first chiefly fecal, often with the presence of small white curds, and are usually strongly acid in reaction. They quickly become liquid and greenish or greenish-yellow, contain increasingly larger amounts of mucus, and at times are blood-tinged. Initially there are evidences of irritability and, at times, stupor and convulsions. These symptoms frequently disappear after the first day or so, but the irritability and restlessness return if dehydration and acidosis develop. The number of stools varies from a few to twenty or more a day. The evacuation is often preceded by pain, and the stools may be expelled with force.

The extent of dehydration and the rapidity of its development depend upon the amount of fluid lost in the stools, the presence or absence of vomiting, and the extent to which fluids are replaced parenterally. In untreated cases there is loss of subcutaneous tissues and elasticity of the skin. The pulse is rapid and weak, and the prostration becomes greater. The output of urine is progressively decreased; the urine has a high specific gravity and often contains albumin and casts. There is invariably some hemoconcentration, which in severe cases becomes marked. Owing to the decrease in renal function and to the hemoconcentration, nonprotein nitrogen levels of the blood are increased, at times to as much

as 100 mg. per 100 ml. or more. Acidosis is usually a prominent manifestation; in untreated cases plasma carbon dioxide levels may be less than 10 volumes per milliliter, and the pH may approach 7. Hypertonic dehydration may be a significant factor, especially when milk feedings have been continued or hypertonic saline solutions are given (p. 187).

Cases which fall in the second category have been variously termed "acute toxic diarrhea" and "alimentary intoxication." They are characterized by an abrupt onset with high fever, often 104° to 106° F., and extreme prostration. Vomiting is frequently severe. An infant who otherwise has been well suddenly becomes extremely prostrated. In some instances there is evidence of irritability, restlessness and even convulsions, but symptoms of collapse are more frequent. The infant in this latter instance is flaccid, and pallor is usually noticed. Respirations are rapid and may be hyperpneic. Diarrhea may not appear for some hours or even a day and, as a rule, is not striking in contrast to the extreme severity of the general symptoms. The fatality rate is extremely high, and death often occurs within the first twenty-four hours. This clinical condition may be the infantile pattern of severe food poisoning. Though acidosis and hemoconcentration are likely to be extreme, such peripheral manifestations of dehydration as loss of subcutaneous tissue and inelasticity of the skin are not prominent in the infants who die in the first day or two of the disease.

**Diagnosis.** Clinical evaluation of the infant with diarrhea is essential for planning treatment. There is no differential diagnosis beyond that of establishing the etiology. Occasionally a lead may be had from the history, indicating the source and nature of the infection or the possibility of food poisoning, but in most instances the etiology can be determined, if at all, only by bacteriologic cultures of the stool and, in infections with the pathogenic strains of *E. coli*, agglutinative studies (p. 344). Cases suspected of being viral in origin can be studied serologically by determinations of antibody levels in acute and convalescent stage serums (p. 388). Samples of several stools of those passed in the first twenty-four hours of observation or, preferably, several rectal swabs at intervals of eight to twelve hours should be plated immediately for culture.

Since the metabolic disturbances of diarrhea in infants are an important part of the

clinical situation, no severe case may be adequately appraised without the assistance of laboratory data (see p. 184).

**Prevention.** Diarrheal disturbances are much more frequent in artificially fed infants than in breast-fed ones. Thus every effort should be made to secure breast feeding for all newborn infants. When artificial feeding is a necessity, the mother should be properly instructed in the sterilization of formulas and in their storage until the time of feeding, so that contamination is prevented. Weaning of breast-fed infants should be avoided during hot weather. During periods of unusually high environmental temperature and humidity or during any febrile disturbance infants should be supplied with adequate amounts of fluid,

and the intake of food should be temporarily reduced. Excessive clothing should be avoided, and the infant should be kept at home and away from visitors.

**Treatment.** This is discussed under the various diarrheal entities. See under Mild diarrhea (p. 189), Acute severe Diarrhea (p. 187), Diarrhea in the Newborn (p. 347), Bacillary Dysentery (p. 437), Amebiasis (p. 613), Salmonella Infections (p. 444), Botulism (p. 1374), Chronic Diarrhea (p. 189), Celiac disturbances (p. 724), Gastrointestinal Allergy (p. 1328,) Congenital Alkalosis of Gastrointestinal Origin (p. 189) and antibiotic and sulfonamide dosages (p. 210).

WALDO E. NELSON

## THE STOMACH AND INTESTINES

### DISORDERS OF THE STOMACH

#### MALFORMATIONS AND MALPOSITIONS OF THE STOMACH

*Malformations*, with the exception of pyloric stenosis, are rare. The stomach may be unusually small and remain so; in such instances there is often increased thickness of the walls. There may be complete atresia at either orifice, or the stomach may be partly divided by a constriction somewhere in its midportion (hourglass stomach). Duplication of the stomach is a rare anomaly; one or both portions may be partially or totally intrathoracic. See page 663 for defects in gastric musculature.

*Malpositions*, though not common, occur somewhat more frequently than malformations. In association with transposition of other viscera, the stomach may be situated on the right side of the abdomen and empty to the left. In diaphragmatic hernia the stomach may be situated partly or completely within the thoracic cavity; with congenitally short esophagus the stomach may be partly in the thoracic cavity. In the latter instance or in the case of abdominal adhesions the stomach may be maintained, as in fetal life, in a vertical or nearly vertical position.

#### CONGENITAL HYPERTROPHIC PYLORIC STENOSIS

Congenital hypertrophic pyloric stenosis is characterized by vomiting beginning as a rule

in the second or third week of life and becoming increasingly projectile, by gastric peristaltic waves, often by a palpable tumor mass at the pylorus, by constipation and by loss of weight. Pathologically, there is hypertrophy and hyperplasia of the pyloric musculature resulting in a tumor mass which constricts the lumen of the pyloric canal and impedes gastric emptying.

The *pathogenesis* of this condition is not understood. In favor of congenital origin is the high incidence of involvement of both of monovular twins, in contrast to the relative infrequency in both of binovular twins.

**Incidence.** By far the majority of cases occur in male infants and usually in the first-born. It has been estimated that the incidence in Sweden is one in 150 male infants and one in 775 female infants. Familial incidence has been observed. Pyloric stenosis has been reported in both of eleven sets of identical twins, whereas there are only two sets recorded in which only one of them had pyloric stenosis. Breast-fed as well as artificially fed infants are affected. Pyloric stenosis is apparently rare in Negro infants.

**Pathology.** The pylorus is elongated, thickened to as much as twice its usual size, and almost cartilaginous in consistency. There is thickening of the muscular coat, principally of the circular fibers, and severe narrowing of the lumen, which explains the difficulty in

FIG. 189. Hypertrophic pyloric stenosis. Elongated pyloric canal in an infant with hypertrophic pyloric stenosis, showing the so-called string sign, the blunt antrum and evidence of retained gastric contents. Hyperactive peristalsis was observed fluoroscopically.

the passage of food (Fig. 189). The stomach is usually dilated, and in long-standing cases there may be hypertrophy of its muscular coat.

**Clinical Manifestations.** Initially there is only occasional vomiting, which may begin within a week or so after birth, more often not until the second or third week. The onset is rarely delayed until the second or third month of life. After a few days the typical manifestations rapidly make their appearance. When fully developed, perhaps no other clinical condition has a more characteristic pattern. The principal manifestations are projectile vomiting, loss of weight, constipation, visible gastric peristaltic waves and a palpable pyloric tumor.

**Vomiting.** Within several days or at most a week after the onset, vomiting becomes projectile. Perhaps in no other conditions is there such forceful vomiting. At times the vomitus may be propelled 3 or 4 feet when the child is lying on his side, and for a foot or more when lying on his back. Vomiting characteristically occurs during or shortly after feeding, but at times as much as several hours later. The frequency varies; in some instances it may be after each feeding, whereas in others it may occur only after two or three feedings. There is apparently no nausea, and the infant will take another feeding immediately. The vomitus consists only of gastric contents, but may be blood-tinged; it is not bile-stained. When the vomitus is blood-streaked, the

possibility of impending massive hemorrhage should be recognized.

**Dehydration.** When vomiting has been persistent for some days, there is dehydration, and loss of hydrochloric acid may be responsible for severe metabolic alkalosis. At such times there is an increase in plasma carbon dioxide content, increase in pH and decrease in serum chloride. There is also a loss of potassium, which is usually reflected by a low serum potassium level. When dehydration is extreme, however, the hemoconcentration may be responsible for sufficient decrease in renal function so that the retention of acid metabolites compensates for the loss of hydrochloric acid, and there is little or no shift to the alkaline side.

**Constipation.** This is a striking feature. At times no fecal matter is passed for days. The stools are characteristically small; occasionally a starvation type of diarrhea develops.

**Loss of weight.** This may be extensive, and the weight may decrease to a level below the birth weight. At such times there is inelasticity of the skin and loss of subcutaneous tissues, and in extreme cases even the fat pads of the cheeks are lost. In such instances the infant has a withered, "old man" appearance.

**Gastric peristaltic waves.** These waves, visible through the thin abdominal wall, are most prominent immediately after ingestion of food or just before vomiting. Occasionally they may be stimulated by deep palpation or friction of the abdominal wall. They are initiated at the left side near the costal margin and pass toward the pylorus, one or two being visible at a time, suggesting the rolling of balls under the abdominal wall; they become smaller as they approach the pylorus (Fig. 190). The waves are usually best observed from the right side with the eyes on

FIG. 190. Gastric peristaltic waves of pyloric stenosis in an infant 3 weeks of age. (Courtesy of Dr. Carl Wagner, Cincinnati.)

a level with the abdomen, and with the light, which should not be too bright, coming from the left side. At times the infant appears to be uncomfortable, but pain is not a prominent feature.

**Pyloric tumor.** The tumor may be palpated in the majority of instances. It is usually situated about midway between the umbilicus and the costal margin, just lateral to the right rectus muscle. It may be situated underneath the lower margin of the liver. The mass is cylindrical and a centimeter or so in diameter. Palpation with the tip of the finger (which should be warm) should at first be superficial, with a rotary motion over the pyloric area (the angle formed by the right rectus muscle with the costal border). If the mass is not located, the fingers are then pressed deeply but gently into the abdomen in this area with a to-and-fro motion while pressure is exerted on the stomach from the left side by the examiner's left hand in order to push the pylorus toward the right and to help to immobilize it. In this maneuver the infant is rolled to his right side. Relaxation of the abdomen is usually best secured just after vomiting and while the infant is being fed. The mass is more likely to be located before the stomach has become distended with food.

**Diagnosis.** In typical cases there is little difficulty in diagnosis, which is established by the characteristic clinical pattern. The rare instances of *congenital atresia of the pylorus* are distinguished by the development of symptoms within a few hours after birth. *Congenital obstructions of the duodenum* may be responsible for projectile vomiting and visible peristaltic waves. When the obstruction is complete, it is apparent a few hours after birth; but if it is incomplete, as, for example, because of external bands or stenosis, it may not become evident for days or weeks after birth. The vomitus contains bile if the constriction is below the ampulla of Vater. Colonic peristaltic waves may at times be mistaken for gastric waves, and gastric waves are occasionally visible in small emaciated infants who do not have pyloric stenosis. *Adrenal insufficiency* in infants (p. 1182) may simulate hypertrophic pyloric stenosis; the absence of a palpable tumor mass and changes in the chemical constituents of the blood aid in differentiating them. *Chalasia* and *achalasia* of the esophagus may be responsible for vomiting in the first few weeks of life, but should be differentiated by roentgenographic studies.

The principal diagnostic difficulty is with

hyperactive infants who vomit frequently and often explosively in the first few weeks after birth. In some instances the vomiting is sufficiently persistent and projectile so that a differential diagnosis is made only after roentgenologic studies. The vomiting often disappears completely, however, when the feedings are given by a different and experienced attendant. In such instances the cause of the vomiting appears to be due to errors of feeding technique, especially to failure to eructate swallowed air. Some infants are easily excited and overactive and vomit readily, frequently with considerable force. It is especially in this latter group that the term "*pylorospasm*" has been used. Since this type of vomiting is controlled by an antispasmodic such as atropine or by prefeeding sedation with phenobarbital, there is justification for the medical treatment of cases in which the diagnosis of pyloric stenosis is not definitely established.

A roentgenologic examination is not necessary in patients with a characteristic clinical pattern, but it may be in early or questionable cases. The examination should be more inclusive than a simple determination of the gastric emptying time, since on occasion little or no gastric contents may pass through the pyloric canal for three or four hours, and total emptying may be delayed much longer in nonstenotic cases. Determination of the prepyloric opening time is of value. Normally this is observed within five minutes after barium has been swallowed. Demonstration of the narrowed pyloric canal (Fig. 190) is the most important roentgenologic sign. It is diagnostic in conjunction with a delayed prepyloric opening time and a delayed emptying time.

**Prognosis.** When the diagnosis is made early in the course of the disease and the infant is properly prepared for operation, the operative fatality rate is less than 1 per cent. There have been no comparable results with medical therapy. That an occasional patient with true pyloric stenosis survives without surgical treatment is apparent from the reports of finding pyloric tumors at autopsy in infants who died of other causes some months after symptoms of pyloric stenosis had disappeared. At best, medical therapy can be expected to require two or three months. With surgery the infant is usually well within two or three weeks. Gastric disturbances in older children and adults have been attributed to the after-effects of pyloric stenosis in infancy, but the data are not convincing. Complete recovery is the rule.

**Treatment.** Relief of the pyloric obstruction by operation as soon as the diagnosis is established and metabolic imbalances are corrected is the treatment of choice. The better results with early rather than late surgical correction, the long duration and frequent unsatisfactoriness of medical therapy, and the dangers of cross infections in infants' wards of hospitals support such a policy.

**Nonsurgical treatment.** Since some clinicians prefer to give medical therapy a trial, and since it is justified for cases of so-called pylorospasm, the procedure is outlined here. Under no circumstances should it be used for the infant with pyloric stenosis who has marked loss of weight or severe alkalosis.

**THICKENED FEEDINGS.** The advantages of thickened feedings are not such as to justify discontinuance of breast feeding. When the infant is artificially fed, cereal or barley flour has been traditionally added to thicken the milk formula. For this purpose a precooked cereal is satisfactory. Feedings may be made of such a thickness that they will pass through nipple holes which have been enlarged to about 2 mm. in diameter. When vomiting occurs shortly after feeding, the feeding should be repeated. Some clinicians believe that vomiting is less frequent after a "small curd formula" than with the thickened feedings. Emptying of the stomach by gastric lavage before a feeding when there is epigastric distention may decrease the chance of vomiting after the succeeding feeding.

**HYDRATION.** Adequate hydration must be maintained and parenteral administration of fluids is often required. The carbon dioxide content of the blood should be measured from time to time in order to avoid development of severe alkalosis.

**DRUGS.** Atropine has been a standard remedy for years, but satisfactory results from its use are rare. Other atropine derivatives have also been used; European clinicians in particular have reported good results with Eumydrin. Wallgren recommends a 0.6 per cent alcoholic solution of Eumydrine which contains approximately 0.1 mg. in each drop of the solution. The initial dose is 1 drop, about twenty minutes before each feeding, the medication being placed directly on the infant's tongue. The dose is then gradually increased until vomiting is controlled or flushing of the face appears, when the dose is decreased. Doses exceeding 3 to 5 drops are rarely administered.

If atropine is given, a freshly prepared

solution should be used. Although infants appear to have a high tolerance for atropine, there are occasional instances of idiosyncrasy. Since these reactions may be lethal, initial doses should always be small, 1 drop of a 1:1000 solution or, preferably, 10 drops of a 1:10,000 solution. The dose is gradually increased until the vomiting is controlled or until flushing of the face, dilatation of the pupils or fever occurs, when the dose should be decreased. When the dose is equal to 10 drops of the 1:1000 solution, this concentration should be used rather than the weaker one.

Some clinicians prefer phenobarbital to atropine, and others give them together. The good results obtained with phenobarbital in so-called *pylorospasm* may be due to a sedative effect in hyperactive infants. In such infants administration of phenobarbital twenty minutes or so before feeding has been effective in controlling vomiting and in facilitating adjustment to a more satisfactory regimen. An initial dose of 10 or 15 drops of the elixir may be prescribed with instructions to increase it gradually to 30 to 40 drops if necessary, unless too heavy sedation results. When vomiting is controlled, the dose should be gradually reduced until administration of the drug is discontinued.

Medical therapy should not be continued for more than a week or two unless there are evidences of benefit from it, and not for this long when the infant continues to lose weight or otherwise does poorly.

**Surgical treatment.** **PREOPERATIVE MANAGEMENT.** No infant should be operated upon without satisfactory preoperative preparation. This consists in adequate hydration, the correction of any anemia by blood transfusions, and the correction of metabolic deficits (see p. 189 and Table 34 for details). Determination of the optimum time for operation is based on clinical judgment and laboratory data. Thiamine chloride, ascorbic acid and vitamin K should be given parenterally prior to operation. It is good practice to empty the stomach by lavage before operation; leaving the tube in the stomach during the operation seems to reduce postoperative vomiting by removal of stomach secretions and swallowed air.

**OPERATION.** The hypertrophied muscles of the pylorus are split without incising the mucous membrane (Fredet-Ramstedt method).

**POSTOPERATIVE MANAGEMENT.** Details of postoperative feeding vary in different clinics mainly in the time of offering the first

feeding. It is general practice to give a non-milk liquid such as a solution of 5 per cent glucose in saline for the first one to three feedings. In our clinic the first feeding of one ounce of 5 per cent glucose in a balanced saline solution is offered to the infant eight to twelve hours after operation, with repetition of it once or twice at intervals of two to three hours, and then a milk formula is substituted (the initial one 10 to 12 calories per ounce, with subsequent ones of an isocaloric mixture, if tolerated) with gradual increase in the amount and in the intervals between feedings until the infant is on an average schedule after four to six days. An occasional infant requires one or two subcutaneous infusions postoperatively, but the majority do satisfactorily without parenteral administration of fluids. Vomiting other than of occasional small amounts of mucus after the first glucose water feeding is unusual. Adequacy of preoperative preparation and gastric aspiration during operation may be factors lessening postoperative vomiting.

## INFLAMMATION OF THE GASTRIC MUCOSA

For gastric ulcer, see Peptic Ulcer (p. 671).

### ACUTE GASTRITIS

This condition is relatively uncommon. It is difficult of diagnosis and is most often demonstrated at autopsy. In general, lesions which come under this heading are associated with infectious diseases or are caused by corrosive agents.

**Infectious Gastritis.** Acute catarrhal gastritis is infrequently demonstrated at autopsy, but may occur in association with a number of infectious conditions such as acute gastroenteritis, thrush and a variety of parenteral infectious diseases. Multiple, small, nonindurated superficial ulcers are occasionally observed in newborn infants dying of a variety of causes or in infants dying of enteritis. Erosive lesions may result at points where an indwelling gastric tube rests against the gastric mucosa. Pseudomembranous gastritis is rare; it is usually seen with diphtheria, but has been observed with smallpox, scarlet fever, sepsis of the newborn infant, and other infectious diseases. Gastric lesions in these conditions are often unsuspected during life, since vomiting and anorexia are frequent symptoms in all of them. Occasionally there is bleeding, and the vomitus contains either fresh or digested blood.

**Corrosive Gastritis.** This form of gastritis is produced by strong acids or alkalis or by other irritants. There are accompanying lesions of the mouth, pharynx and esophagus. When sufficient quantities of an irritant are swallowed to produce an extensive gastritis, the prognosis is grave. Collapse occurs quickly, and death is likely within a few hours, or life may be prolonged for two or three days and then death results from exhaustion. If the child survives, there may be symptoms of chronic gastritis. In most instances the esophageal lesion is the one of most importance.

**Treatment.** The general treatment of burns from acids and alkalis is discussed on page 1380, and of esophageal lesions on page 644. There is no special treatment for acute catarrhal gastritis, except that of the infection responsible for it. Coarse foods should be avoided; when there is persistent vomiting, parenteral administration of fluids and nutrients is required.

## GASTRIC DILATATION

**Acute Dilatation.** Acute dilatation of the stomach, and of the intestine as well, may occur during the acute stages of pneumonia and other severe infections, after abdominal and thoracic operations, during peritonitis, with diabetic acidosis and intestinal obstruction, and occasionally without discoverable cause. Dilatation is a serious condition, especially when it occurs with pneumonia and peritonitis. Temporary relief can be provided by deflation through a stomach tube or, when there are accumulated gastric contents, by lavage. The use of the Wangenstein suction apparatus in postoperative conditions has been helpful in avoiding and in treating gastric dilatation. Prostigmin, subcutaneously, may be of some benefit.

**Chronic Dilatation.** Chronic dilatation may follow a mechanical obstruction such as stenosis of the pylorus, or one from external traction by adhesions or by pressure of a tumor in the pyloric area. It may also be a manifestation of chronic gastritis. During infancy the most frequent cause is atony of the muscular wall in such conditions as rickets and extreme malnutrition.

The treatment depends upon the cause. A mechanical obstruction should be relieved. Chronic nutritional disturbances should be corrected. Overfeeding should be avoided, but an adequate intake of calories, vitamins and minerals must be maintained.

## GASTRIC HEMORRHAGE

Bleeding from the stomach may occur in association with purpura, hemophilia, hypoplastic anemias, leukemia, scurvy, cirrhosis of the liver, peptic ulcer, esophageal varices associated with obstruction of the portal or splenic vein, polypoid adenoma of the stomach or congenitally short esophagus. Traumatic rupture of the stomach, injury from a swallowed foreign body, generalized infections, diabetic acidosis and persistent vomiting as in pyloric stenosis may also be responsible for gastric hemorrhage.

**Differential Diagnosis.** Blood which is vomited may originate elsewhere than in the stomach; it may come from the nose, mouth, esophagus, lungs or the fissured nipple of the nursing mother. Blood expectorated from the lungs without swallowing is frothy. When hemorrhage from the stomach is copious, the blood is usually bright red, but when bleeding has taken place slowly and the blood has remained for some time in the stomach, the color will be dark brown or black (coffee ground vomitus).

**Prognosis and Treatment.** The prognosis depends upon the cause, but extensive gastric hemorrhage is usually serious.

In extensive hemorrhage immediate steps should be directed toward its control, treatment of shock and replacement of lost blood. The child should be put at absolute rest, an ice bag should be placed over the epigastrium, and morphine given hypodermically. When the hemorrhage is extensive, blood transfusions should be given as soon as possible to replace the lost blood. When the bleeding is continuous, gentle but constant aspiration through a Levin tube may aid in putting the stomach at rest, remove the irritation from gastric secretions and provide an index of the extent of the bleeding. Every effort should be made to determine the cause.

## NEOPLASMS OF THE STOMACH

Neoplasms of the stomach are extremely rare in early life; primary carcinoma, sarcoma, lymphosarcoma, lipomas, polypoid adenomas and teratomas have been observed.

## FOREIGN BODIES IN THE STOMACH AND INTESTINES

An object which reaches the stomach will in most instances pass through the gastrointestinal tract. Certain types of foreign bodies,

however, are potentially dangerous. Needles, hairpins or bobby pins pass easily through the esophagus on their long axis, but may be unable to round the turns of the duodenum, where they become fixed and eventually perforate the intestine. Such potentially dangerous foreign bodies can usually be removed gastroscopically. Special attention should be paid to safety pins in the stomach. If they are small, they will probably pass without difficulty, whether open or closed. If they are large, either closed or open, peroral removal is safe and is indicated.

If the foreign body has passed through the pylorus into the intestine, its progress should be observed daily by means of roentgenograms, and every stool should be examined for its presence. The stool can be placed in a fine-meshed sieve and disintegrated by allowing water to run through the sieve with some force. If the roentgenogram shows the foreign body to move progressively down the intestinal tract, perforation is not likely. If it remains stationary for a week, surgery is indicated because of the dangers of ulceration and perforation of the bowel. If at any time such signs of perforation as tenderness, rigidity, pain, nausea or vomiting develop, surgery is indicated immediately. The diet should be normal, with no change from that to which the child has been accustomed. The bizarre roughage and wool or cotton diets sometimes recommended are valueless and may be extremely dangerous. Laxatives are contraindicated, since the accelerated activity of the intestine increases the danger of perforation.

## GASTRIC PERFORATION

Perforation of the stomach or adjacent portions of the esophagus or duodenum is relatively uncommon in infants and children; it is more often recognized at autopsy than during life. Recently there have been a number of reports of spontaneous rupture of the stomach in newborn infants, some of which were recognized during life and repaired surgically with recovery of the infant.

Among the causes, perforation of ulcers is the most readily explained; these include ulcers secondary to an indwelling lavage tube, those associated with systemic diseases, usually acute ones, Rokitansky-Cushing ulcers and chronic gastric and duodenal ulcers (p. 671). Of particular interest are the cases of spontaneous perforation in apparently healthy newborn infants. Some of these have not

been explained at autopsy by any lesion other than the rent; rarely some have been associated with obstructive lesions, such as atresia of the pylorus, but a significant number have occurred in infants with defects of the gastric musculature. The perforation has occurred through these defects, usually along the greater curvature.

Initial *symptoms* are not characteristic. Vomiting is usually the first one; both the vomitus and the stool may contain blood. Abdominal distention occurring suddenly in an infant should always suggest the possibility of perforation at some site in the gastrointestinal tract, especially if there is obliteration of liver dullness. Cyanosis may appear if the distention is sufficient to interfere with respiration. Manifestations of shock can appear rapidly. A roentgenogram of the abdomen taken in an upright position revealing a pneumoperitoneum is diagnostic of perforation.

*Treatment* consists in surgical repair as quickly as the infant can be prepared. Post-operatively, Wangensteen suction may be useful for two or three days, and fluids, and blood if necessary, should be given parenterally (see p. 191).

## BEZOARS

Occasionally infants and children acquire the habit of swallowing hair from their head or from dolls, brushes, hair pillows or the like, or they may swallow fur, wool or cotton from wearing apparel or blankets. Though some of this material may be passed through the intestines, when the habit is persistent, there is an accumulation in the stomach with formation of the so-called *hairball* or *trichobezoar*. The *symptoms* are indefinite, but indigestion and gastric distress are often present. The tumor mass is often palpable, and may give a soft crackling sensation on palpation. A roentgenogram taken after administration of barium may disclose a characteristic

Fig. 191. Hairball (trichobezoar) in the fundus of the stomach of a girl 5 years of age; it is outlined by barium. The child was admitted to the hospital for intestinal obstruction resulting from a portion of the trichobezoar which had detached from the gastric mass and become impacted in the ileum.

picture (Fig. 191). A portion of the bezoar may be dislodged and subsequently become impacted in the intestine and cause obstruction. The *diagnosis* may be suspected from observation of the child in the act of swallowing these materials, and hair may occasionally be observed in the mouth or the stools. The tumor mass should be removed surgically. The child's mental and psychologic status should be evaluated, and treatment provided as indicated.

*Phytobezoars* are accumulations of fibrous or mucilaginous materials such as that in persimmons and various tar products. The accumulation is usually rapid in comparison with that of the hairball.

## INTESTINAL DISORDERS

### MALFORMATIONS AND MALPOSITIONS OF THE INTESTINES

A variety of congenital anomalies of the intestinal tract are responsible for partial or complete obstruction. The majority of these malformations involve the rectum and the

anus (p. 680), with the duodenum next in order of involvement: the jejunum, the ileum and the colon are less often affected. The principal anomalies may be grouped under the following headings: (1) intrinsic obstruction of the lumen by stenosis, atresia, aplasia or absence of a segment of the gut; (2)

anomalies of position which include (a) variations in mesenteric attachments resulting at times in volvulus or in bands of tissue constricting the intestine, (b) malrotation of the intestine with or without associated volvulus and constricting bands (*malrotation may be responsible for intestinal obstruction at any age, for recurrent abdominal pain throughout childhood or for the clinical manifestations of the celiac syndrome*); (c) transposition of the intestines in conjunction with transposition of other viscera; (3) diverticula, of which the principal one is Meckel's; (4) anomalies of size such as microcolon; (5) anomalies of innervation, as manifest by aganglionic segments (megacolon); (6) duplications, which may occur in practically any portion of the digestive tract, viz., esophagus, stomach and small and large intestines; (7) intra-abdominal hernias through omental and mesenteric defects, through rings formed by remnants of the omphalomesenteric duct, and through diaphragmatic defects; and (8) external hernias, which include those into an omphalocele, through the inguinal canal, and through various external muscular defects.

## INTESTINAL OBSTRUCTION

### CONGENITAL INTESTINAL OBSTRUCTION

Obstruction of the intestinal tract at birth may be complete or partial. A completely obstructive lesion is most likely to be either an atresia or an aplasia of a segment of the intestine, although complete obstruction may occur from some of the lesions which characteristically produce only partial obstruction. From an anatomic standpoint congenital obstructive lesions of the intestines can be divided on the basis of whether the obstructing factor is intrinsic or extrinsic.

#### *Intrinsic Obstructions*

Aplasia  
Atresia  
Stenosis  
Aganglionic segments  
Meconium ileus

#### *Extrinsic Obstructions*

Volvulus of the midgut, usually with malrotation of the cecum  
Extrinsic duodenal bands, commonly with malrotation of the cecum and its fixation in the right upper quadrant  
Constricting bands in the region of the ligament of Treitz  
Duodenal compression by the mesenteric artery  
Herniations  
Intra-abdominal through

#### *Extrinsic Obstructions*

Omental and mesenteric defects  
Rings formed by remnants of omphalomesenteric duct  
Diaphragm  
Extra-abdominal  
Annular pancreas  
Duplications of segments of small or large intestine

**Clinical Manifestations.** Clinically, the anatomic feature of a congenital intestinal obstruction is often not definable and is of secondary importance, since operation is *always* indicated. An attempt to locate the lesion, however, is of considerable importance, since it may determine the surgical approach. The differences in operative techniques for a duodenal atresia and in imperforate rectum are readily appreciated.

When the obstruction is *complete*, there should be no difficulty in clinical recognition, but when incomplete, there may at times be considerable difficulty. With complete obstruction symptoms appear shortly after birth. If the obstruction is in the duodenum, the symptoms may become manifest within a few hours; if it is in the large intestine, the symptoms may be delayed for a day or so. They consist characteristically in vomiting, abdominal distention and an absence of feces. Meconium stools may be passed, but, on microscopic examination, absence of lanugo hairs and cornified epithelial cells, which are swallowed with the amniotic fluid, is suggestive evidence of a complete obstruction (*Farber test*). This test is a valuable one, but care should be taken to obtain the specimen for examination from the center of the meconial mass. Epithelial cells from the rectum and perianal area may adhere to the outside of the stool and be misinterpreted as swallowed epithelial cells.

When the obstruction is *incomplete*, symptoms may appear shortly after birth or be delayed, depending on the degree of obstruction. Enough food may pass the constriction to permit fecal discharge.

Obstruction in the duodenal area is responsible for epigastric distention and, at times, for gastric waves similar to those of pyloric stenosis. The distention may not be persistent, however, since it may be relieved by vomiting. The vomiting may be projectile, and the vomitus will contain bile if the obstruction is below the ampulla of Vater.

Obstructions in the lower ileum, colon or rectum will be responsible for more generalized distention, often with bulging of the flanks. When the liver dullness is obliterated,

there is a strong possibility that intestinal perforation has occurred. Vomiting with lower bowel obstruction may be delayed a day or so, but eventually may become fecal in type. Meconium ileus is described on page 331, aganglionic megacolon on page 674, and anal and rectal obstructions on page 680.

**Differential Diagnosis.** This is principally from other causes of persistent vomiting, abdominal distention and obstipation. In *atresia of the esophagus* swallowed food is vomited immediately; when there is a *fistula* between the trachea and lower esophageal segment, there is air in the stomach. The esophageal obstruction can be demonstrated by inability to pass a catheter or by roentgenologic examination with the use of iodized oil. If the obstruction is in the duodenum, pyloric stenosis may be suspected because of the gastric peristalsis and because the distended duodenum may simulate a pyloric tumor. The symptoms of *pyloric stenosis* are rarely manifest, however, until the second or third week of life, and the vomitus does not contain bile, as it does when the duodenal obstruction is below the ampulla of Vater.

In stenosis of the lower ileum or colon the vomiting appears later and is eventually fecal. In newborn infants a paralytic ileus may develop within a few days after birth in association with general sepsis or peritonitis and simulate lower intestinal obstruction.

Valuable information on the location of congenital obstructive lesions in the intestine may be obtained by roentgenograms of the abdomen without ingestion of contrast material, since in completely obstructive lesions there will be distention of the bowel above the obstruction and there may be a series of fluid levels with superimposed gas in the distended loops. When the use of contrast material is considered necessary either by mouth or by enema, some material other than barium should be used.

Insufflation of air into the stomach under fluoroscopic control may localize duodenal and other obstructive lesions. Under usual circumstances air is demonstrable roentgenographically in the stomach of the normal infant immediately after birth. Within an hour the proximal portion of the small intestine is outlined, and, between the first and third hours, the entire small intestine and segments of the colon are demonstrable. The distal parts of the colon may be visualized as early as the third hour. Up to the time of the first feeding there is a progressive increase in the amount of air in both the small and

large intestines. After the first feeding there is a relative decrease in the amount of air in the small intestine and an increase of it in the colon.

**Prognosis.** When a complete obstruction is not relieved promptly, the clinical course is rapid. Vomiting is persistent, dehydration, loss of weight, and prostration become marked, and the infant dies within a few days. When the obstruction is not complete, the infant may survive for weeks; minor obstructions may be compatible with life even without treatment. Recovery from both complete and incomplete obstructions can be expected in the majority of instances with early diagnosis and appropriate management.

**Treatment.** Not every obstructive lesion is amenable to surgery, but every patient is entitled to the opportunity for surgical repair. Infants can even withstand massive resection of the small intestine when the lesion or lesions necessitate it.

Preoperative preparation, including constant gastric aspiration, and postoperative care are of the greatest importance, especially in relation to the correction of dehydration and electrolyte deficits and to the maintenance of fluid balance and nutrition by parenteral means (p. 195).

#### ACQUIRED INTESTINAL OBSTRUCTION

There are a number of causes of acquired intestinal obstruction. Paralytic ileus, which is secondary to acute infections, especially pneumonia and peritonitis, and to uremia and electrolyte imbalance of any origin, is a frequent cause. Pneumonia is probably the most frequent cause of paralytic ileus in infants; peritonitis, the most frequent cause in older children. Incarcerated inguinal hernias and intussusception are the most frequent mechanical causes of intestinal obstruction in infants. Intestinal obstruction may also result from adhesions produced during the course of an acute peritonitis from which recovery occurred, or the adhesions may result from a chronic peritonitis such as a tuberculous one. Other causes are foreign bodies in the intestine, including fecal concretions and inspissated meconium in the newborn infant (p. 331); tumors of the bowel or those pressing on it, such as mesenteric cysts, and masses of roundworms. Rectal stricture from lymphogranuloma venereum rarely occurs in children.

Certain congenital anomalies responsible for intestinal obstruction may not manifest themselves until some time after birth. These

include intra-abdominal herniations, volvulus resulting from malrotation of the intestine, and duplications of the bowel.

### INTUSSUSCEPTION

Intussusception or invagination of a portion of the intestine into an adjacent part competes with incarcerated inguinal hernia as the most frequent acquired mechanical cause of intestinal obstruction in infancy. Though rare in the first month of life, over half of the cases occur in the first year and most of the remainder in the second. It is two to three times more common in males than in females.

**Etiology.** In most instances intussusception develops in healthy infants, its production supposedly being favored by the unusual mobility of the cecum and ileum and by the hyperperistalsis present in early life. *Agonal intussusception* is presumably caused by the loss of muscular tone which precedes death.

**Predisposing factors.** Infrequently there are demonstrable predisposing factors such as drastic purgation, diarrhea, constipation, abnormalities such as Meckel's diverticulum, invagination of the appendix, abdominal injuries, hemorrhage or ulceration of the gut, foreign bodies, large fecal masses or parasites in the lumen of the intestine, polyps, cysts, papillomas or other intestinal tumors, and swelling of the lymphatic tissue of the intestinal wall.

**Pathology.** The invagination is almost invariably from above downward. The upper portion, the intussusceptum, slips into the lower, the intussusciens, pulling the mesentery with it (Fig. 192). The dragging upon the mesentery causes the intestine to assume a curved, sausage-shaped form, with the concavity toward the mesenteric attachment at the spinal column. The bowel can remain patulous, the circulation of blood in it be preserved, and occasionally the intussusception is spontaneously reduced. Usually, however, swelling begins promptly as a result of edema and hemorrhage secondary to venous engorgement, with resultant complete intestinal obstruction. Incarceration of the intussusceptum occurs, which becomes irreducible through adhesive inflammation between the adjacent serous surfaces, and finally strangulation takes place, with necrosis of the part. The strangulated portion may perforate or rarely become entirely separated by gangrene and be discharged through the anus, the lumen of the gut thus becoming re-established. Agonal intussusception shows little

evidence of inflammation or swelling and is without clinical significance.

**Clinical Forms.** Intussusceptions are classified according to their situation as enteric, colic, ileocolic and ileocecal. Mixed forms may occasionally occur; a double intussusception is observed in less than 10 per cent of cases. Ileocecal intussusception is the most frequent form; the cecum with the ileum behind it passes into the colon.

**Clinical Manifestations.** In typical cases there is a sudden onset, with severe paroxysmal pain, vomiting, and restlessness. In between the initial paroxysms of pain the infant may be quite comfortable. These symptoms are usually followed within twelve to twenty-four hours by the rectal passage of bloody mucus and by a rapidly developing and increasingly severe prostration. The abdomen is at first soft, later distended, and often tender. The fecal matter in the colon and rectum may be evacuated during the first several hours. After this time fecal excretions are small, or more often they do not occur, and little if any flatus is passed.

**Pain.** Characteristically, pain is paroxysmal, occurring at frequent intervals and attended by straining efforts if the intussusception reaches the rectum. Early the pain is usually intense and causes loud outcries; later it may be evidenced only by grunting sounds.

**Blood and mucus in the stools.** Blood generally appears in the first twelve hours, but at times not for one or two days or even not at all. Stools containing blood and mucus are often described as currant jelly stools. Failure of evacuation of fecal matter and of flatus is most common in enteric invagination, in which, too, hemorrhage may be delayed or entirely absent.

**Vomiting.** This is usually more frequent at the beginning. Stercoraceous vomiting is uncommon and generally not until late in the course.

**Tumor.** The elongated, sausage-shaped tumor may often be found early in the course,

FIG. 192. Diagrammatic representation of the production of intussusception. (Kemp: Diseases of the Stomach, Intestines and Pancreas.)

FIG. 193. Intussusception in an infant. The obstruction is evident in the proximal transverse colon. Contrast material between the intussuseptum and the intussusciens is responsible for the coil-spring appearance.

even in the first few hours, and rarely may reach the anus by the second day. It is usually possible to palpate it rectally by bimanual examination; during a paroxysm of pain the tumor temporarily increases in size and approaches nearer to the anus. When protruding from the anus, the intussusception may have the appearance of a rectal prolapse or a polyp. The presence of bloody mucus on the finger as it is withdrawn after rectal examination is supportive evidence.

**Prostration.** The initial restlessness is rapidly replaced by exhaustion and prostration. In the untreated case prostration is likely to be extreme by the second day, and the temperature may reach  $106^{\circ}$  to  $108^{\circ}$  F.

**Atypical forms.** Intussusception rarely may exist for a number of days (*chronic form*) without the usual acute symptoms. Such cases are more likely to occur in infants during a severe diarrheal disturbance or in older children, when intussusception is a rarity. The obstruction is not complete, and the circulation in the mesentery is not entirely obliterated. Pain and vomiting may not be severe, and there may not be bloody mucous stools. Diarrhea may be present instead of constipation. The symptoms in these chronic cases may come on in separate attacks and suggest recurrent ileocolitis. There is always the danger of sudden complete strangulation.

*Chronic recurrent intussusception* is rare;

instances have been observed, especially in older children, in which repeated intussusceptions are spontaneously reduced.

**Differential Diagnosis.** The diagnosis is not difficult in the average case when there are sudden developments of abdominal pain, vomiting, tenesmus, bloody stools without fecal matter, prostration and an abdominal tumor. The mass may be obscured after several hours by abdominal distention or rigidity unless examination is made under an anesthetic. Enteric intussusception seldom presents a discoverable tumor, there is no tenesmus, and these cases cannot be distinguished with certainty from intestinal obstruction of other causes. The bloody, mucous movements of intussusception may suggest *colitis*; conversely, *colitis* may be supposed to be intussusception. In *nonthrombocytopenic purpura* hemorrhage into the lumen and walls of the intestine may simulate intussusception, but evidences of purpura elsewhere aid in distinguishing it. Intussusception may, however, be a complication of purpura. With *Meckel's diverticulum* there may be blood in the stool without other symptoms, or, if there is a diverticulitis, it may simulate appendicitis.

Contrast roentgenograms, after a barium enema, may demonstrate the intussusception (Fig. 193).

**Prognosis.** Untreated cases in infants are nearly always fatal; the chances of recovery are directly related to the duration of the intussusception before reduction. The majority of infants will recover if the intussusception is reduced within the first twenty-four hours, but the mortality rate rises rapidly after this time, and recoveries are unusual when reduction is deferred to the third day. In the uncommon less acute cases the course, if untreated, may be as long as two or three weeks. In such instances death usually results from exhaustion and rarely from peritonitis. Spontaneous reduction may occur; the incidence, of course, is not known. The rate of recurrent attacks in infants is apparently not more than 2 or 3 per cent.

**Treatment.** The intussusception should be reduced as soon as the patient can be prepared for operation by treatment for shock and correction of water and electrolyte imbalances (p. 186). Experience in our clinic in reduction of the intussusception has been limited to the direct surgical approach. Ravitch and others use a nonoperative technique in selected cases. An adequate comparative evaluation of the operative and non-

operative methods is not available; in each the skill and experience of the operator are important factors.

The advantages of the operative method are (1) certainty of reduction, (2) demonstration of any "lead points" (Meckel's diverticulum, polyp, and the like, which occur in 5 to 8 per cent), (3) avoidance of delay when the initial nonoperative method is not effective, and (4) possibly a lower recurrence rate.

When the nonoperative technique is to be used, Ravitch stresses that the operating room must be in readiness for immediate surgery should the nonoperative attempt be unsuccessful and that the reduction by barium enema should be performed by the surgeon under fluoroscopic observation. His technique for reduction by hydrostatic pressure is as follows:

The stomach is aspirated, intravenous administration of fluids is started, and a nonlubricated Foley bag catheter is placed in the rectum and inflated. The buttocks are compressed tightly and taped with adhesive plaster. A barium solution is then allowed to flow by gravity into the colon from a height of not more than 3 to 3½ feet above the fluoroscopic table. The abdomen is *not touched* during the procedure. If the intussusception is reduced, it is manifest by free filling of the small intestine, disappearance of the mass, passage of flatus or feces and improvement in the infant's condition. Charcoal is then administered by mouth, and its recovery in an enema six hours later is further evidence of intestinal patency. If there is any doubt about the completeness of the reduction, an exploratory operation is performed immediately through a McBurney's incision.

## DIVERTICULOSIS AND DIVERTICULITIS

Diverticulosis refers to the presence of multiple outpouchings of the intestinal tract, usually in the colon, but occasionally in the small intestine. With the exception of Meckel's diverticulum, most diverticula are of the false type, i.e., saccular pouches, the walls of which are largely devoid of the muscular coat of the intestine. Their etiology is unknown, but they seem to result from weakness of the intestinal wall. The condition is usually benign, often being unproductive of symptoms. Occasionally there is general abdominal discomfort such as that associated with spastic colitis, but in the majority of instances one may doubt whether the diverticula are responsible for the symptoms. The condition, though more common in adults, may occur in children.

*Diverticulitis*, or inflammation of the diver-

ticula, may take place, giving rise to nausea and vomiting, fever, leukocytosis, and abdominal tenderness and rigidity usually in the lower left quadrant. Perforation occasionally occurs with resulting peritonitis. Treatment is symptomatic; if perforation occurs, it is that of peritonitis.

## DISORDERS ASSOCIATED WITH MECKEL'S DIVERTICULUM

The omphalomesenteric duct, which connects the ileum to the umbilical vesicle or yolk sac and ordinarily atrophies and disappears by the fifth or sixth month of fetal life, may persist in all or part of its course and be responsible for a variety of anomalies (Fig. 194). Of these, the most frequent is Meckel's diverticulum, which is estimated to occur in 2 to 3 per cent of all persons, more frequently in males than in females.

**Pathology.** Meckel's diverticulum is located on the ileum. The wall of the diverticulum is similar to that of the adjacent intestine, as is its lining membrane, although cells of other tissues may make up a part of the membrane. The most frequent type of aberrant tissue is identical with gastric mucosa. Less frequently there are pancreatic cells, including those of the islets of Langerhans, or cells of duodenal or colonic mucosa.

**Clinical Forms.** The diverticulum is usually not responsible for any symptoms, but perhaps the most common one is hemorrhage from the bowel with or without other manifestations. It may, however, be responsible for a variety of clinical conditions, the principal ones being diverticulitis, intestinal obstruction and umbilical lesions.

**Diverticulitis.** This condition is relatively infrequent; about one third of the cases occur in children, the incidence being higher in males than in females. The pathogenesis and the pathologic changes may be similar to those of appendicitis. The course may be acute or chronic. When the onset is abrupt and is accompanied by abdominal pain, nausea, vomiting, often constipation, fever, leukocytosis, abdominal tenderness and muscular resistance, the differential diagnosis from appendicitis may be impossible except by operation. In some instances there is blood in the stools, which may provide a clue to the diagnosis. Hemorrhage may also occur into the peritoneal cavity. Perforation with secondary peritonitis is an occasional complication, as is intestinal obstruction, which may be produced by compression of the intestine by the inflammatory mass or by intussusception.

FIG. 194. Diagrammatic representation of structures derived from remnants of the omphalomesenteric duct. *a*, Cord extending between umbilicus and ileum; *b*, cyst suspended between umbilicus and ileum; *c*, cyst suspended from umbilicus; *d*, Meckel's diverticulum with cord extending to umbilicus; *e*, everted mucocoele attached by cord to ileum; *f*, fecal fistula between ileum and umbilicus; *g*, Meckel's diverticulum with free intraperitoneal cord; *h*, enterocystoma; *i*, stenosis from excessive evolution. (Brennemann: Practice of Pediatrics. W. F. Prior Co., Vol. 3.)

A *peptic ulcer* situated in aberrant gastric mucosa is occasionally observed in, or in the vicinity of, a Meckel's diverticulum. The method of production of the ulcer, its course and the symptoms produced are similar to those of gastric and duodenal ulcers. Hemorrhage from the bowel is the most frequent symptom; it may be intermittent and present over long periods of time or may be abrupt and extensive. Perforation of the ulcer may be responsible for peritoneal bleeding or peritonitis. Rarely a Meckel's diverticulum

can be identified roentgenographically after a barium meal.

**Intestinal obstruction.** Meckel's diverticulum may be responsible for intestinal obstruction in several ways. Strangulation of the intestine may result from herniation of a loop of intestine through a ring formed by the atrophied cord of the diverticulum. Volvulus of the intestine may be secondary to anomalies associated with Meckel's diverticulum, or the diverticulum may invaginate itself into the intestine and be responsible for a true

enteric intussusception. Littre's hernia is a rare condition in which a Meckel's diverticulum protrudes, along with the adjacent portion of the intestine, into a hernial sac, such as that of an inguinal, femoral or umbilical hernia. If the diverticulum becomes inflamed, as is likely, it becomes adherent to the hernial sac and is thus responsible for incarceration.

**Umbilical lesions.** A variety of lesions may occur (Fig. 194). If the omphalomesenteric duct remains patent, the fistulous tract from the intestine may discharge intestinal contents through the umbilicus. If the intestinal terminus is closed, there is only a mucoid secretion. A cystic mass may be formed in the tract when both ends of the duct are closed, and at times it may protrude through the umbilicus.

**Treatment.** In practically all disturbances of Meckel's diverticulum, operation is indicated. The kind of operation obviously depends upon the type of anomaly and its complications. If, during an abdominal operation for other conditions, a diverticulum is discovered, it should be removed if the situation otherwise permits.

## PEPTIC ULCER

### (GASTRIC AND DUODENAL ULCERS)

Gastric and duodenal ulcers occur at all ages of infancy and childhood, including the neonatal period. Although usually recognized only at autopsy, in a fairly large number the diagnosis has been established during life (see Gastric Perforation, p. 663). There is no good approximation of their incidence, but they are generally considered to be infrequent.

The *symptoms* related to the ulcer may dominate the clinical picture, but often the symptoms are obscured by some other serious disease, e.g., meningitis, gastroenteritis, sepsis or extensive burns (Curling's ulcer); ulcers associated with cerebral lesions of various types (Rokitansky-Cushing ulcers) are commonly diffuse areas of digestion of the esophagus or fundus of the stomach, but typical crater-like peptic ulcers may also be associated with cerebral lesions.

Duodenal ulcers are more frequent than gastric ones and are usually located on the posterior wall of the duodenum. Ulcers in infants are more likely to be acute than chronic, and signs and symptoms are often limited to the occurrence of melena and hematemesis or to those of perforation and peritonitis; vomiting may be projectile, owing to severe pylorospasm.

*Chronic primary peptic ulcers* occur more frequently after infancy, the incidence being higher in late childhood. The symptomatology is varied. In some instances there are only vague digestive complaints such as abdominal discomfort with or without localization or relation to eating. In some instances the pain is more characteristic of that in adults, being relieved by eating in most instances, but occasionally aggravated by it. Paraumbilical pain would appear to be more frequent in young children, and epigastric pain in older ones. Vomiting is less frequent than pain; in a few instances cyclic vomiting has been a manifestation. Blood may be present in the vomitus or stools. The frequency with which children with peptic ulcers are reported as being tense, compulsive and maladjusted speaks strongly for a psychogenic disturbance as a contributing etiologic factor.

In the *differential diagnosis* it must be ascertained that blood has not entered the stomach and intestine from outside sources, as from the nose or mouth or, in nursing infants, from the nipple of the mother (see p. 337 for laboratory test), and other causes for melena must be sought. Pyloric stenosis, Meckel's diverticulum, appendicitis, intestinal polyposis, gastrointestinal allergy, parasitic diseases and the various blood dyscrasias must all be considered diagnostic possibilities. Roentgenograms may show a characteristic appearance of the duodenum. Sometimes duodenitis occurs without ulceration, and the roentgenogram shows poor filling and rapid emptying of the duodenal cap.

**Treatment.** Extensive hemorrhages require transfusions and continuous but gentle gastric aspiration when there are no signs of perforation (see Gastric Hemorrhage). Immediate laparotomy is indicated when perforation has occurred. Treatment of the chronic peptic ulcer is similar to that recommended for adults and consists of a bland diet with frequent small feedings with or without antacids and antispasmodics. Banthine has been used extensively in adults. Psychologic evaluation and appropriate therapy are considerations of first importance. Surgical repair should be reserved for those children whose lesions cannot be controlled by other means.

## REGIONAL ENTERITIS

Regional enteritis is a localized chronic lesion of the lower intestinal tract which may eventually be controlled spontaneously or may be slowly progressive. In the latter event in-

testinal obstruction may be produced, or there may be discharging sinuses which open through the abdominal wall into any of the hollow viscera of the abdominal cavity or into the vagina. Occasionally there are perirectal, rectal or rectovaginal fistulas. The incidence is highest in young adults, but cases have been observed in children.

**Etiology.** The cause is unknown; low grade infection and allergy have been suggested as possible causes.

**Pathology.** The lesion is usually limited to the terminal ileum, but may extend into the jejunum or even into the cecum and colon. Occasionally, multiple involved areas may be separated by relatively intact bowel. The wall of the bowel is thickened, hyperemic and indurated, and extensions of mesenteric fat partially encircle the serosa. The lumen is narrowed and the mucosa ulcerated; fistulas may extend from the ulcers into the abdominal wall, the mesentery or adjoining loops of bowel. Histologically, there is severe edema of the submucosa, with fibrosis in the chronic stages. The lymphoid tissue of the involved bowel is hyperplastic, as are the mesenteric lymph nodes. Granulomatous foci or isolated giant cells are often present.

**Clinical Manifestations.** The onset is occasionally acute, with symptoms suggestive of acute appendicitis. More often, however, the onset is insidious, and the course is that of a low grade chronic infection without specific complaints. There may be abdominal pain, failure to gain or loss of weight. Though there may be mild diarrhea, there are often intermittent periods of constipation. During the periods of diarrhea the stools contain mucus and pus and, at times, blood. Vomiting is not common. There is frequently a low grade fever and anemia. Abdominal examination may not reveal any evidence suggestive of the lesion unless there is a tender fixed mass in the lower part of the abdomen. The mass is more often situated on the right than in the midline or on the left side. The presence of an external fistula should always suggest the possibility of regional enteritis. Complete or partial intestinal obstruction may be the presenting symptom.

**Differential Diagnosis.** When the onset has been abrupt, appendicitis may be suspected. In the chronic stage, chronic colitis, tuberculosis and abdominal actinomycosis should be considered. On occasion Hodgkin's disease or lymphosarcoma may be responsible for symptoms suggestive of regional enteritis. The possibility of chronic colitis can usually be

eliminated by proctoscopic examination or by means of a barium enema. The characteristic "string sign" of regional enteritis may be demonstrated by this method.

**Prognosis.** The prognosis for life is usually good, but the course of the disease is persistently chronic, and spontaneous cures are infrequent; this is especially true when fistulous tracts have developed.

**Treatment.** No treatment is entirely satisfactory. Initially elimination diets may be tried with the possibility that the lesion is an allergic one. There are differences of opinion concerning surgical treatment, but it should be reserved for cases which do not respond to medical therapy. One of the broad-spectrum antibiotics may be given a trial and is recommended for the immediate preoperative and postoperative periods if radical surgery is undertaken. Corticosteroids have been used, but their value is not established.

### PNEUMATOSIS INTESTINALIS

This is a rare condition characterized by multiple gas-filled cysts in the wall of the bowel. The cysts may be located in the small intestine, the colon, or both; in infants they

FIG. 195. Lateral roentgenogram of the abdomen of an infant with aganglionic megacolon involving the entire colon. Pneumatosis of the colon was demonstrated ante mortem and post mortem in the walls of the rectum and sigmoid; note the apparent double contour of the intestinal walls (arrows).

are predominantly submucosal. The condition may occur at any age. In infants it is often associated with intrinsic disease of the gastrointestinal tract, e.g., enterocolitis, pyloric stenosis or congenital abnormalities. No symptoms directly related to pneumatosis in infancy are recognized. The diagnosis has been established roentgenographically (Fig. 195) or at laparotomy, but more frequently at autopsy. The pathogenesis of the cysts is not known, but may be related to mucosal defects with escape of intestinal gases into the lymphatics and wall of the bowel. Death appears to result from some cause other than the pneumatosis.

## MEGACOLON

The terms "megacolon" and "Hirschsprung's disease" have been used interchangeably to include most enlargements of the colon except those resulting from partial obstruction by obvious anatomic lesions in the anorectal area, such as anorectal stenosis (p. 680). The demonstration that many examples of megacolon are secondary to an absence of

myenteric ganglion cells in the distal, constricted segment of the colon has created a separate clinical entity, designated neurogenic or congenital aganglionic megacolon. Psychogenic factors resulting in obstipation, at times with encopresis (p. 654), may also be responsible for enlargement of the colon. The classification of megacolon by Garrard and Richmond is a useful one:

- Megacolon due to gross anatomic lesion
  - Stricture secondary to surgical repair of imperforate anus
  - Anorectal stenosis
  - Intrinsic or extrinsic obstructing tumors
- Aganglionic megacolon (neurogenic)
- Psychogenic megacolon

Since patients with megacolon of either the first or second category can expect improvement from surgical or other mechanical therapy, and since those with psychogenic megacolon not only would be harmed by such treatment, but also might be helped by psychotherapy, the importance of differentiation is obvious.

#### CONGENITAL AGANGLIONIC MEGACOLON

##### (HIRSCHSPRUNG'S DISEASE)

Congenital absence of parasympathetic ganglion cells from the intramural plexus of a portion of the intestinal tract, usually the distal end of the colon, is responsible for the entity described here. The involved section of the gut is narrowed and devoid of peristaltic activity, and is thus responsible for accumulation of fecal material above it. As a result the uninvolved portion of the intestine (usually colon) becomes greatly dilated and hypertrophied and is responsible for abdominal distention, which with the obstinate constipation creates the typical clinical pattern.

Congenital megacolon is more common in males than in females. In a series of 200 cases Swenson has observed three families with more than one child with aganglionic megacolon.

**Pathology.** A narrowing of a portion of the rectum or rectosigmoid is usually demonstrated. Proximal to the narrowed segment, the colon is tremendously dilated and filled with feces and gas, and the muscular coat is hypertrophied. In long-standing cases this dilated portion of the intestinal wall may become thin. Ulceration of the mucosa is an infrequent complication in older children, but it is not rare in infants; perforation is unusual.

Histologic examination of the constricted portion of the rectosigmoid colon reveals an absence of the parasympathetic ganglion cells

of the intramural plexus, whereas they are present in the proximal dilated portion.

In the majority of instances (90 per cent) the aganglionic segment of the bowel is located in the rectum or rectosigmoid for a length of 4 to 25 cm. Instances of involvement of the entire colon, of portions of the small bowel and rarely of variously situated segments with absence of ganglion cells have been reported.

**Clinical Manifestations.** In newborn infants the symptoms of congenital megacolon may present a variety of patterns. The symptoms may be present at birth with failure to pass meconium, or may appear during the first week of life and be those of partial or even apparently complete intestinal obstruction with vomiting, constipation and abdominal distention. Roentgenograms of the abdomen will reveal fluid levels indicative of intestinal obstruction. Relief of symptoms may occur after a rectal examination or an enema with the appearance of normal stools for a short time. Bile-stained and even fecal vomiting may occur. In such cases the infant becomes dehydrated, and there is loss of weight. In some instances diarrhea may be the predominant symptom in the neonatal period and may occur in association with such symptoms of obstruction as vomiting (often fecal) and abdominal distention.

When the symptoms during early infancy are not prominent, the subsequent course is marked by increasingly obstinate constipation. Eventually the child presents the typical appearance of congenital megacolon with a distended abdomen. Laxatives may be effective initially in producing evacuations, but this is true for only a short time. Stools may not be passed for days and when passed may consist of small pellets, be ribbon-like or have a fluid consistency. Enemas are frequently necessary to produce evacuations. Progressive abdominal enlargement results, owing to the dilatation of the colon with feces and gas. The abdominal wall becomes thin, the superficial veins are prominent, peristaltic patterns of the colon are frequently visible and audible, and large, soft fecal masses may be readily palpated. Rectal examination usually reveals an absence of fecal material despite a large impaction of the colon. In mild cases the nutrition may not be greatly disturbed, but in the more severe ones there is likely to be loss of subcutaneous tissue and failure to grow. In such instances the combination of wasted extremities and a large protruding abdomen creates a typical appearance. A hypochromic anemia

FIG. 196. A, Roentgenogram with barium in the distal colon shows narrowed segment in the rectosigmoid area with a relatively normal-appearing rectum. Note the dilatation of the colon proximal to the narrowed segment. B, Represents a tracing of A, and shows the approximate extent of aganglia in black; actually, the area of aganglia does not stop abruptly and usually extends into the dilated portion for a short distance. (From Keefer and Mokrohisky, Radiology, Vol. 63.)

is often a complicating factor. Intermittent attacks of intestinal obstruction resulting from impaction of feces may be associated with pain and fever.

**Diagnosis.** Anorexia, constipation, abdominal distention and vomiting in the absence of a readily demonstrable organic obstruction are suggestive of congenital megacolon in a newborn infant. The symptoms may appear soon after birth, but in some instances an "overflow type" of diarrhea may develop to confuse the picture. Differentiation of megacolon from *cystic fibrosis of the pancreas* can be accomplished by examination of the duodenal secretions for trypsin and by the "sweat test." Demonstration (see below) by appropriate roentgenographic studies of the narrowed segment of the rectosigmoid, which is characteristic of congenital megacolon, is possible at all ages, but is likely to be less definitive in infants less than six months of age than in older ones.

In children the diagnosis is suggested by a history of constipation and abdominal distention existing from infancy. Spontaneous bowel movements are infrequent, and response to laxatives and enemas is characteristically unsatisfactory. Rectal examination reveals an absence of fecal material despite a large impaction of the colon.

Roentgen examination of the colon with barium according to the technique of Neuhäuser reveals in the most common type a narrowed segment just proximal to the anus and distal to the dilated colon. Only a small amount of barium should be injected slowly

through a small catheter whose tip is inserted barely beyond the anal sphincter while the patient in an oblique position is being observed under the fluoroscope (Figs. 196 and 197). The characteristic narrowing of the rectosigmoid portion will be missed if the lower colon is flooded with too much barium. The possible existence of mechanical obstructions such as stenosis or stricture of the anus and membranous valvelike lesions in the rectum or sigmoid should be eliminated by

FIG. 197. Aganglionic megacolon in infant 3 weeks of age. The extent of the aganglionic segment is evident, as is the dilatation of the sigmoid above it. Such clear-cut demarcation of the aganglionic section is not always demonstrable in infants of this age.

proctoscopic and sigmoidoscopic examinations.

Megacolon may at times be confused with the *celiac syndrome*, which may be differentiated by the more severe degree of malnutrition, by the fatty, diarrheal stools and by roentgenographic examination. Differentiation must also be made in children with chronic constipation, and particularly in those described earlier with psychogenic megacolon. Roentgen examination of the urinary tract should also be obtained, since megaloureters have been demonstrated in some instances in conjunction with congenital megacolon.

Swenson has described a technique of rectal biopsy as an aid in the diagnosis of difficult or unusual cases, especially in newborn infants in whom the constricted portion of the colon may not be demonstrated by roentgenographic studies.

**Treatment.** Cleansing of the bowel is usually a difficult task, but retention enemas of 3 to 4 ounces of mineral or olive oil followed by repeated colonic irrigations with an isotonic saline solution will usually remove most of the fecal accumulation. The rectal catheter should be inserted beyond the constricted segment. Attacks of syncope, shock and even death have been attributed to water intoxication following the use of tap water and soap suds enemas. Magnesium poisoning has been reported following retention of enemas of magnesium sulfate in patients with congenital megacolon. Thus the use of solutions other than isotonic saline solution for rectal irrigation should be avoided.

Removal of the narrowed segment of bowel by the "pull-through" surgical technique devised by Swenson results in relief of symptoms and a return to normal bowel habits in the majority of instances. During operation it is essential to ascertain from biopsies of the bowel that ganglion cells are present in the proximal portion of the resected bowel before the final anastomosis is made.

If an infant's condition does not warrant the extensive procedure of a "pull-through" operation, a colostomy should be performed. It is desirable to make the colostomy in the distal portion of the colon containing normal ganglia. Preoperative preparation, with correction of any water and electrolyte deficits and anemia, and adequate maintenance postoperatively are essential for success. Later, when the infant is in good nutritional state and has been gaining weight, the "pull-through" form of resection of the bowel can be performed.

## APPENDICITIS

**Incidence.** Appendicitis is rare in the first two years of life, but has been observed as early as three days. There is a slowly increasing incidence up to twelve years of age; the greatest incidence is between fifteen and thirty years. Boys appear to be somewhat more susceptible than girls.

**Etiology.** Obstruction seems to be the principal predisposing factor. Fecal concretions are a recognized form of obstruction; other forms are not so easily demonstrated, but are thought to result from swelling in response to acute respiratory infection or, less commonly, to systemic infections such as rheumatic fever, measles, varicella or scarlet fever, or to allergy. The small lumen of the appendix makes it vulnerable to obstruction from such causes as kinking, scarring from previous inflammation and the anatomic narrowing near the base. On occasion appendicitis occurs in association with enteric infections which fail to subside completely. Streptococci and, less commonly, *Staphylococcus aureus*, either alone or mixed with coliform bacilli, are the organisms most frequently isolated from infected appendices. Pinworms occasionally cause inflammation.

**Pathology.** Inflammation begins in the mucosa, which may ulcerate; the wall is edematous and infiltrated with neutrophils; the lumen is distended, often enough to impair the blood supply and produce gangrene and perforation. In milder types there may be mucosal ulceration without obstruction.

Bacteria may escape through a perforation or even the gangrenous wall to produce diffuse peritonitis or an abscess confined by adherence of adjacent omentum and intestines.

**Clinical Manifestations.** The classic triad of abdominal pain, vomiting and constipation is diagnostic when associated with localized tenderness, increased muscular resistance in the right lower quadrant and the absence of peristalsis. In children, however, the clinical manifestations are often not so typical; when the child is unable to relate in detail the type and location of his discomfort, the diagnosis may be difficult. The pain varies greatly in intensity and may be paroxysmal or more or less constant. It may be, and often is, generalized, but there is usually some localization, most often in the right lower quadrant or the umbilical region, less often in the epigastrium or the pelvic region.

Slight to moderate increases in temperature and pulse rate are commonly present.

The appendix may lie below, behind or on either side of the cecum, behind the small intestine or omentum, over the brim of the pelvis or even deeply in the pelvis adjacent to the rectum or bladder, and, on rare occasions, may extend to or be located on the left side. In those positions in which other viscera are interposed between the appendix and the anterior abdominal wall, physical findings are often slight. When the appendix lies in the pelvis, even as high as the promontory of the sacrum, a gentle rectal examination in a moderately cooperative child will often reveal a definite difference in pain response on the right and left sides, and bimanual palpation may reveal the actual indurated area. Gentleness and explanation are of particular importance in this part of the examination.

Infrequently the onset may be with diarrhea, vomiting and abdominal pain. Diarrhea is more likely to be a manifestation when the appendix is located in the pelvis or when gastroenteritis is a precursor.

The most reliable diagnostic features are (1) persistent abdominal pain of more than twelve hours' duration associated with vomiting—the latter is rarely absent in children; (2) localized or "point" tenderness in the right lower quadrant or umbilical region; (3) absence of peristalsis, unless diarrhea is present or food or laxatives have been given; (4) leukocytosis of 12,000 to 15,000 with a relative increase of immature polymorphonuclear cells; and (5) absence of acute intrathoracic or urinary tract disease. The pres-

ence of acute nasopharyngitis should cause one to be cautious in attributing abdominal findings to appendicitis.

**Differential Diagnosis.** The diagnosis of appendicitis is frequently difficult in infants and children, because atypical cases are common, and because other conditions may simulate acute appendicitis. When there is any reasonable diagnostic doubt, and there frequently is, it is safer to err on the side of laparotomy, except in the presence of pneumonia. Though many conditions may simulate appendicitis, only a few are common. During early infancy these include so-called colic, gastroenteritis, pyelitis and intussusception. Later there are the common acute digestive upsets of children, food poisoning, gastroenteritis, pyelitis, acute mesenteric adenitis, pneumonia, rheumatic fever, certain of the acute contagious diseases and acute nasopharyngitis.

Pneumonia involving the right lung may be responsible for referred pain and tenderness and even muscular spasm in the right lower quadrant, and abdominal symptoms may be present before the pulmonary ones are clearly evident. Rapid shallow breathing, grunting expirations, movement of the alae nasi with respiration and, when present, cyanosis, of course, favor pneumonia. The pain on pressure over the abdomen is frequently cephalic of the cecal region, and tenderness is diffuse, being present on superficial palpation and frequently disappearing on deep pressure. The roentgenogram of the chest may reveal pulmonary consolidation.

Less frequent diagnostic possibilities are tuberculous mesenteric adenitis or peritonitis, Henoch's purpura, inflammation of a Meckel's diverticulum, and a twisted pedicle of an ovarian cyst.

**Complications.** Whether localized abscess formation (p. 688) and diffuse secondary peritonitis (p. 687) are to be considered complications or part of the natural course of acute appendicitis may be debatable, but they are the only common sequels. Perforation occurs earlier and more frequently in children than in adults, and there is less tendency for the infection to become localized. This failure to localize has been attributed to the relatively small size of the omentum in young children. A pelvic abscess occasionally occurs, but subphrenic abscess is rare. Less common complications are paralytic ileus and thrombophlebitis.

**Prognosis.** There is great danger in postponing operation for appendicitis, since local

or diffuse peritonitis consistently follows perforation, and almost negligible risk attends operation before perforation. Even when perforation has occurred, the mortality rate may be less than 1 per cent. This low rate is probably due to several factors, including improvements in preoperative preparation, operative technique, anesthesia, parenteral fluid therapy and antibacterial therapy.

**Treatment.** The appendix should be removed as soon as the diagnosis is established and the child has been placed in as good condition as possible for surgery. Preoperative preparation includes hydration (see p. 195), reduction of temperature below 102° (rectal) even if mild hypothermia is required, and of the pulse rate below 120, and the use of antibiotics and analgesics. As much as six to eight hours can be spent advantageously to decrease the risk of anesthesia. When perforation has occurred, the treatment of peritonitis must be instituted. Even if the diagnosis is disproved by operation, it is usually best to remove the appendix.

A small muscle-splitting incision in the region of the appendix is the preferred procedure. After this type of operation children are usually out of the hospital within four or five days, return to school in two weeks, and are allowed athletic privileges after six weeks.

During observation, when there is some uncertainty about the diagnosis, an enema may be helpful, but food or laxatives should be scrupulously avoided, owing to the danger of hastening perforation.

## MESENTERIC LYMPHADENITIS

### ACUTE MESENTERIC LYMPHADENITIS

Acute mesenteric lymphadenitis is frequently associated with an acute infection of the upper respiratory tract, especially of the pharynx. So much attention has been directed

to this combination of inflammatory lesions, and the possibility that it may simulate acute appendicitis, that the physician may fail to recall that both acute and chronic involvement of the mesenteric lymph nodes may also be associated with infections of the appendix and the intestines.

**Clinical Manifestations.** There is fever, abdominal pain, vomiting and at times constipation or diarrhea. The pain may be spasmodic, is often in the right lower quadrant, but may be in any part of the abdomen.

**Differential Diagnosis.** When the pain is in the right lower quadrant and there is localized tenderness and muscular resistance, the possibility of appendicitis cannot be eliminated except by laparotomy. Certain diagnostic differences have been suggested, such as a tendency in adenitis for the area of tenderness to shift when the patient is moved from side to side in contrast to a fixation of the area of tenderness in appendicitis, and the presence of tenderness along the route of the mesentery on a line extending from McBurney's point upward to the left of the umbilicus in mesenteric adenitis. However, the diagnosis of mesenteric lymphadenitis can be made only by exclusion of other causes, and, unless the child is operated upon, only a presumptive diagnosis can be made at the termination of the illness.

**Complications.** Suppuration of the lymph nodes is rare, but it may be responsible for localized or generalized peritonitis.

**Treatment.** Whenever appendicitis is a reasonable possibility, operation is indicated, since the danger of operation in mesenteric adenitis is much less than is the danger of rupture of an inflamed appendix.

### CHRONIC MESENTERIC LYMPHADENITIS

Chronic infections of the lymph nodes may be sequels to an acute infection, or the involvement may be low grade from the onset. In addition to the conditions which may be responsible for acute adenitis, tuberculosis and histoplasmosis are etiologic possibilities. Involvement of the lymph nodes is practically a constant accompaniment of all chronic intestinal infections, but is usually overshadowed by the clinical manifestations of the primary disease. Noninfectious lymph node involvement is seen in association with Hodgkin's disease, lymphosarcoma and with neoplasms of any of the abdominal or pelvic organs.

## CHRONIC COLITIS

If the cases of chronic colitis caused by known etiologic agents, such as those of chronic amebic and bacillary dysentery, are eliminated, most of the remaining cases can be placed in two groups: (1) the so-called irritable colon (chronic spastic colitis or chronic mucous colitis) and (2) chronic ulcerative colitis of unknown etiology. The irritable colon or chronic spastic colitis is not a common condition in children (p. 654).

## CHRONIC ULCERATIVE COLITIS

**Etiology.** This is a chronic inflammatory condition of unknown etiology in which, as the term implies, there is a tendency to the production of chronic indolent ulcerations. Possibly a number of different organisms may be responsible for this condition, but proof of any one is lacking. Occasionally, amebic or bacillary dysentery may become chronic; it has been suggested that many cases of chronic ulcerative colitis may begin as an acute infection caused by one of these etiologic agents with the chronic phase caused by some other organism. Food allergy has been considered to be the primary cause in some cases. Deficiency of vitamins and minerals is a secondary rather than a primary factor. It has been estimated that about 10 per cent of all cases occur in children under fifteen years of age. There appears to be little doubt but that psychogenic factors have a big role in the maintenance of the chronic course and in causing acute exacerbations; it may also be that they are an etiologic factor.

**Pathology.** Any part or all of the colon may be involved, and the ileum is involved in approximately one third of the cases. The mucosa may be largely denuded, only a few irregular patches of epithelium remaining, or multiple longitudinal ulcers may be joined to each other at irregular intervals as a network of ulcers. The remaining mucosa often contains soft, edematous pseudopolypoid nodules. The ulcers are commonly superficial, extending into the submucosa, but they may penetrate the muscularis. In long-standing cases there is extensive fibrosis of the submucosa, and both the internal diameter and the length of the colon are decreased.

**Clinical Manifestations.** The characteristic symptom is the frequent passage of small stools which fairly consistently contain considerable amounts of mucus, pus and blood. At times true diarrhea may intervene and the bowel movements be large. Extensive hemorrhage from the bowel is an occasional complication. There may be no pain and no abdominal tenderness, but in some instances there are tenderness, cramps and tenesmus. Prolapse of the rectum is an occasional complication, vomiting is not particularly common, and fever is absent or occurs only irregularly. The appetite may be unaffected, but in some instances there is anorexia. The emaciation is often extreme. The skin may be dry and rough. There is almost invariably an anemia; though there may be little change in the total white blood cell count, there is likely to be a preponderance of immature granular forms. The erythrocyte sedimentation rate is usually increased. Nutritional edema may be due to a low serum protein level.

**Diagnosis.** Diagnosis of the lesion is established by the clinical pattern, by failure to isolate a specific etiologic agent, by direct visualization of the rectum and sigmoid through the sigmoidoscope and by roentgenographic examination after barium enemas. Though the roentgenographic appearance varies somewhat, there are frequently areas of localized spasm, and in well advanced cases there is loss of haustral markings with the production of the so-called lead pipe appearance. The possibilities of chronic amebic or bacillary dysentery, tuberculous enteritis, gonococcal proctitis and lymphogranuloma venereum should be considered.

Evaluation of the psychosomatic problem should be made by a competent child psychiatrist. The child is rarely, if ever, well adjusted. There is a variety of behavior patterns, including disturbed parent-child relationships in the majority of instances. In the average situation the psychosomatic aspect appears to be the most important one.

**Course and Prognosis.** The course is chronic with periods of transitory improvement and exacerbations and is usually measured in years. A period of six months or so without symptoms should elapse before it is assumed that recovery has taken place. In occasional instances, however, relapses have occurred even after two or three years. Death usually results from exhaustion, rarely from perforation of the colon.

**Treatment.** There is no specific therapy,

but considerable relief can usually be provided. The diet should be a soft bland one with a low residue. Owing to the poor absorption of minerals and vitamins, these should be provided in concentrated form in several times the usual daily requirements. Purgatives and drastic cathartics should be avoided. Kaolin or Kaopectate may provide some relief from the tenesmus, but the effect is not great; bismuth appears to be of little benefit. Small retention enemas of oil or of a mixture of 3 per cent aluminum hydroxide and 15 per cent kaolin may provide some symptomatic relief. Blood transfusions should be given for the anemia. The results of sulfonamide and antibiotic therapy have not been impressive. Vaccines, either autogenous ones or those prepared from the diplostrep-tococcus described by Bargen, have been used, but it is doubtful whether they have been effective. Ileostomy may be justified in persistent cases, but once established, it is usually permanent. There is lack of unanimity of opinion about colectomy, but the results are such as to justify it only as a last resort. During acute exacerbations medical colectomy

may be achieved by using a double-lumen tube of the Miller-Abbott type passed to the ileocecal region. This permits liquid feeding and aspiration to prevent the entrance of material into the colon. Temporary relief is often achieved with one of the corticosteroids; such therapy may be a valuable adjunct, but must be individualized. Perhaps the most encouraging results are to be expected from a well balanced program based on joint pediatric and psychiatric management of the child and his total situation, which includes the family group.

## ANUS, RECTUM AND SIGMOID

Anomalies of the anus and rectum are comparatively uncommon. They occur approximately once in every 5000 births and comprise about 1 per cent of all congenital anomalies. They are somewhat more common among males than females and are commonly associated with other anomalies. The following classification of anal and rectal anomalies has been found useful:

### Anus

1. Absence of orifice (imperforate anus)
  - Membranous occlusion
  - Mural occlusion
2. Stenosis of the anal canal
  - Membranous
  - Mural
3. Abnormal location

### Rectum

1. Nonfistulous
  - Absence of ampulla
  - Absence of supra-ampullary segment
2. Fistulous
  - Rectovesical fistula
  - Recto-urethral fistula
  - Rectovaginal fistula
  - Rectoperineal fistula

## MALFORMATIONS OF THE ANUS

**Pathogenesis.** Absence of the anal orifice or stenosis of the canal (types 1 and 2) results from improper absorption of the anal plate during the eighth week of gestation. Abnormal location of the anus (type 3) occurs with undevelopment or overdevelopment of the urorectal septum. The usual malformation is that of anterior malposition of the anal canal, occurring when the perineal body is inadequately formed by the continued down-growth of the urorectal septum.

**Diagnosis.** *Imperforate anus* is obvious by inspection at birth. Complete membranous occlusion of the anus can be detected by palpation of the rather thin anal membrane which gives a sensation of resiliency, suggesting that the rectal pouch is slightly cephalad. If means are not taken to open the anus, signs of bowel obstruction become manifest.

*Stenosis* (anorectal) may be present in any part of the anal canal, or it may extend its entire length. The constriction may be crescentic or annular in shape and centrally or laterally placed. The symptoms are propor-

tionate to the degree of narrowing and may include dribbling of meconium, ribbon-like stools, constipation, mucoid or bloody discharge in association with straining, abdominal distention owing to enlargement of the colon (megacolon) and restlessness. Occasionally there may be only slight straining at stool and constipation, and the child may even reach adolescence before the condition is detected. The diagnosis is established by digital examination and endoscopically.

*Fistulas* occurring with anal malformations may be detected by inspection or probing or by the injection of a radiopaque substance. Most fistulas associated with anal anomalies are recognized by passage of stool or flatus through them.

*Abnormal location of the anus* usually occurs anterior to its normal position; it may not be detected for some time after birth. In the female fecal contamination of the vagina is the usual sign.

**Treatment.** A partially persistent anal membrane may be excised completely or incised and the free margin sutured to the fibers of the sphincter ani muscle. It is advisable to perform a posterior sphincterotomy, a partial incision of the sphincter muscle bundle in the posterior commissure, when any residual stenosis exists. Mural stenosis of the anal canal usually is best treated with some form of anoplasty. These are all minor operative procedures which result in better function than do simple incision and repeated dilatation.

Completely imperforate anal plates may be incised with cruciate incision, and the skin edges trimmed, or the tip of each quadrant may be sutured lightly to the sphincter muscle.

An abnormally located anal canal and rectum can be transplanted to their normal location by means of a modified Rizzoli procedure. An adequate perineum or rectosigmoid septum must be constructed with the levator ani muscles, or the rectum will tend to resume its misplaced position in later years.

## MALFORMATIONS OF THE RECTUM

**Pathogenesis.** Absence of the distal portion of the rectum (type 1) would seem to be the result of persistence of the solid stage of either the ampulla or the supra-ampullary portion rather than destruction of the rectum by a resorptive process as has been postulated.

The fistulous malformations of the rectum (type 2) usually occur in conjunction with absence of the ampullary segment (anomalies of type 1), but may also occur with anal malformations. It has not been established whether the incomplete downward extension of the mesenchymal urorectal septum or a primary failure of the cloacal duct to disappear is responsible for anomalous connections between the rectum and the genitourinary tract in the male. In the female, connections between the rectum and the genital tract are formed during the descent of the region of attachment of the müllerian ducts to the posterior wall of the urogenital sinus. Such fistulas may connect the rectum with the vagina or the uterus; the latter connection is rare.

**Diagnosis.** In anomalies with absence of the ampullary segment it is obvious that there is an imperforate anus, but the level of the rectal pouch and the amount of intervening tissue are the points in question. Palpation of the anal area indicates that there is a greater barrier than mere persistence of the anal plate. The amount of intervening tissue is determined by the inversion roentgenographic technique (Fig. 199).

Absence of the supra-ampullary segment may not be suspected until signs of bowel obstruction are apparent. Digital and proctoscopic examination should confirm the existence of the blind distal pouch; the inversion roentgenographic technique is also helpful here.

When the blind rectal pouch is fairly high and cannot be easily mobilized from the perineum, and when signs of bowel obstruction are present, a transverse colostomy is indicated immediately. Definitive reconstructive procedures are then usually deferred until the child is at least three years of age.

In the reconstruction of rectovaginal fistulous malformations the Rizzoli procedure is used. When possible, the fistulous tract and a small portion of the distal rectum are exteriorized over a large mushroom catheter for the anticipated retraction which frequently results, rather than suturing the rectal mucosa to the skin margins primarily. Usually the redundant bowel can be excised and the anal canal reconstructed as a minor operative procedure seven to eight days after the initial operation. If the perineal body is carefully reconstructed during this procedure, the likelihood of anterior recession of the rectum is minimal.

FIG. 198. Rectal malformations. (Bacon and Sherman: Arch. Surg., Vol. 64.)

FIG. 199. Wangenstein-Rice roentgenologic technique for demonstration of the position of the blind colonic pouch in the case of an imperforate or absent rectum. The infant is held head downward, causing the intestinal gas to rise to the blind end of the gut. A, Roentgenogram of child in upright position, showing transverse level of gas. The level of the obstruction is not demonstrated. B, The level of the obstruction is apparent when the roentgenogram is taken with the child in the inverted position. The site of the anus is marked by a lead disk.

### FISSURE IN ANO

Fissure in ano, or anal ulcer, is a slitlike tear in the anal canal. It is usually associated with cryptitis and is one of the most common proctologic disorders in infancy and childhood. Predisposing factors are anal stenosis, trauma, irritation by *Oxyuris vermicularis*,

perianal eczema and passage of large scybalous masses. The possibility of a tuberculous, syphilitic or lymphogranuloma venereal lesion should be considered when multiple lesions are present.

**Clinical Manifestations.** Difficulty in defecation and crying associated with it are the usual symptoms. Sparse, bright red bleeding

may be observed. Occasionally there may be a limp suggestive of a lesion in the hip joint.

**Treatment.** Mineral oil by mouth, instillations of warm olive oil into the rectum before defecation with a small rubber-tipped syringe and a dietary regulation to soften the stools tend to diminish irritation of the fissure. Gentle introduction of the lubricated, gloved finger twice daily lessens sphincter spasm. Hot sitz baths, three times daily, especially after defecation, are also helpful. If the sphincter is not spastic, topical applications of 5 per cent silver nitrate twice weekly may be beneficial. Chronic lesions with undermined edges and associated crypts should be excised under anesthesia. Postoperatively, hot sitz baths and 1 per cent gentian violet applications should be given until healing is complete.

## PRURITUS ANI

Irritation from coarse, moist or unclean undergarments is the most common cause of anal itching, but anal fissures and oxyuriasis (p. 579) are also frequent causes. Other causes include gastrointestinal allergy, uncontrolled diabetes, constipation, diarrhea, procidentia or prolapse of the rectum, and foreign bodies. Nocturnally accentuated itching is the salient feature; it results in scratching, restlessness and irritability.

**Treatment** consists in proper cleanliness, dry, nonirritating garments and removal of the predisposing cause. The anal area should be cleansed by washing or with soft cotton rather than with toilet paper. As an aid in keeping the parts dry, the following powder is useful:

Phenol ..... 0.2 gm. (3 grains)  
Starch powder ..... 15.0 gm. (½ ounce)  
Zinc oxide powder, to make . . . 30.0 gm. (1 ounce)  
Sig: Powder anus several times daily

## PROLAPSE AND PROCIDENTIA OF THE RECTUM AND SIGMOID

*Prolapse* is abnormal descent of the mucous membrane of the rectum with or without protrusion through the anal orifice; *procidentia* is abnormal descent of all the coats of the rectum and/or sigmoid with or without protrusion through the anus. These conditions are most common between the ages of three and five years. The infantile rectum lies on a lower plane than the other pelvic organs, which exert downward pressure on the rectum. This anatomic arrangement, com-

bined with the effect of the nearly vertical infantile sacrum, predisposes to prolapse. Any factor causing suddenly increased intra-abdominal pressure may precipitate abnormal descent of the bowel wall. Malnutrition with consequent absorption of ischiorectal fat is a contributory factor. Protrusion at stool initially recedes spontaneously, but later necessitates manual replacement. Bleeding and the passage of mucus may occur. The protruding mass varies from bright to dark red; it may be as much as 6 inches in length, and may be spherical or sausage-shaped. In prolapse the striations or furrows radiate from the center of the anal aperture, in contrast to the circular, concentrically arranged rosette of procidentia.

**Treatment** of the underlying cause is essential; attention should be directed to dietary correction of constipation and proper toilet training as well as to the treatment of any existing disturbance, such as parasitic infection, diarrhea or polyps. Oral administration of mineral oil, rectal instillations of olive oil and strapping the buttocks together with adhesive tape, having first placed a cotton ball over the anal area, may be helpful. Local inflammation of the mucosa may be treated with 25 per cent aqueous instillations of Ichthyol or 10 per cent krameria solution twice daily.

**Reduction of protrusion** is aided by pressure with hot compresses. Cold packs are contraindicated. An easy method of reduction is to cover the finger with a piece of toilet paper, introduce it into the lumen of the mass, gently push it into the rectum and then immediately withdraw it. The toilet paper adheres to the mucous membrane, thus permitting release of the finger; the paper, when softened, is later expelled. Maintenance of the child in an inverted (head-low) position during the reduction may be useful, especially in procidentia. In prolapse of the mucous membrane, but not in procidentia, injection of sclerosing substances into the submucosa is of value. One-half cubic centimeter of 3 per cent quinine and urea hydrochloride or 1 per cent sodium morrhuate solutions may be injected circumferentially at weekly intervals. For intractable cases perineal operation is indicated. In procidentia of the rectum and sigmoid abdominal sigmoidopexy is required.

## ANORECTAL ABSCESES

The most common type of anorectal abscess occurs in the ischiorectal fossa. Infection

usually gains entrance through the anal crypts and the preformed spaces. The symptoms are pain and swelling. Defecation is painful, and the child is unable to sit on the affected part. The temperature is not markedly elevated unless the perirectal space is invaded. Diagnosis is based on presence of a painful swelling overlying the ischiorectal fossa, with redness, heat, induration and fluctuation. Treatment consists in immediate incision and drainage under anesthesia. Hot sitz baths, three times daily, are helpful in the post-operative period.

## FISTULA

An anorectal fistula is an abnormal communication between the anorectum and some adjacent tissue, viscus or skin surface. All noncongenital fistulas are preceded by abscess formation, usually originating from an infected crypt of Morgagni situated at the anorectal line. In infants and children there is usually a single communicating tract. There is frequently a history of one or more incisions into the abscess.

The *symptoms* are those of a painful swelling which recurs intermittently, followed by a purulent discharge. Diagnosis is based on the presence of an opening into the skin beside the anal orifice into which a probe may be introduced (Fig. 200).

*Treatment* is by complete excision of the tract. Care must be taken to incise rather than excise the sphincter in order to prevent incontinence. The operative wound should

FIG. 200. Complete anorectal fistula in a child 15 weeks of age; probe demonstrating external and internal openings. (Bacon: Anus, Rectum and Sigmoid Colon. J. B. Lippincott Company.)

not be sutured or packed. The results, with proper technique, are excellent.

## HEMORRHOIDS

Hemorrhoids are rare in infancy and only infrequently encountered in children. The most common cause is increased abdominal pressure from straining, crying and coughing associated with repeated fecal impactions, constipation and diarrhea. Hemorrhoids in children are usually single, but may be multiple, and they may be of the external or internal variety. Pain, protrusion and bleeding are the usual symptoms. Associated conditions such as constipation and diarrhea should be corrected. When there is protrusion, hot compresses are usually effective. Operation is seldom indicated except for an acute external thrombosis.

## NEOPLASMS

### BENIGN TUMORS

With development of proctosigmoidoscopy, growths of the rectum and sigmoid colon have been more readily demonstrated in infants and children. The majority of these prove to be adenomatous polyps. The presence of numerous eosinophils, dilated cystic mucosal glands and a more diffuse infiltrate of leukocytes tends to distinguish the adenoma of childhood from the adenoma of the adult. Rectal bleeding in children in the absence of a blood dyscrasia is strongly suggestive of an adenomatous polyp. Rectal bleeding in infants is more apt to result from other causes. Bleeding usually is not extensive and tends to occur at the time of defecation; the blood is bright red. Pain is uncommon. Polyps which are situated low in the rectum and have a long pedicle may protrude through the anus. Other benign tumors such as hemangioma and lymphoid hyperplasia may be encountered. Adenomas in the rectum or sigmoid colon can be identified through the sigmoidoscope and/or by double air-contrast, barium enema roentgenograms.

*Treatment* consists in removal of the adenoma. If it is the sessile type located in the rectum, and satisfactory evidence of benignity is established, the growth may be electrodesiccated. Sufficiently pedunculated polyps of the rectum may be removed by an electric snare. Polypoid lesions above the peritoneal reflexion in the sigmoid require excision by abdominal colotomy. Sessile processes, which are usually detected by umbilication of the bowel wall, are best removed by segmental resection.

**MALIGNANT TUMORS**

Malignant neoplasms of the rectum and colon are extremely rare in children, less than forty authentic cases of primary sarcoma and carcinoma in children under twelve years of age having been reported. Malignant tumors occur more often in the rectum than in the sigmoid or anus. The symptoms in order of frequency are abdominal pain, bleeding, constipation, rectal pain, diarrhea, lumbar pain and loss of weight. Digital examination, proctosigmoidoscopy and roentgenographic studies will establish the diagnosis. All tissue removed should be examined microscopically. Radical extirpation is the treatment of choice.

## **CONGENITAL DIMPLES, SINUSES, CYSTS AND TUMORS OF THE SACROCCYGEAL REGION**

**PILONIDAL SINUS AND CYST**

*Pilonidal sinus* is a congenital defect which probably results from faulty coalescence or invagination of the skin ectoderm in the midline over the sacrococcygeal region during early embryonic development. It is characterized by formation of a tract in which are collected the products of dermal activity. Infection enters through the original site of invagination or through aberrant tracts which are manifest after puberty. A *pilonidal dimple* is commonly encountered, but is asymptomatic. Pilonidal cysts and sinuses do not cause symptoms unless infection has occurred. The presence of swelling, heat, redness, tenderness and fluctuation over the sacrococcygeal region is characteristic of an infected sinus. Purulent material may be discharged from one or more openings. If infection occurs, total excision should be performed. (See page 1106 for complications within the spinal canal.)

**DERMOIDS AND TERATOMAS**

Dermoid tumors, or teratomas, are the most common sacrococcygeal tumors in infants and children and are trigeminal in origin. They are classified as congenital tumors. Dermoid cysts do not usually become manifest until adult life, when by increased size, pressure or suppuration they produce symptoms. Teratomas are usually manifest at birth, forming a large skin-covered mass posterior to the rectum. They are more common in females than in males. It is important to differentiate teratomas from meningoceles; the meningocele is usually smaller and does not

increase in size in proportion to the infant's growth as does the teratoma. The teratoma usually displaces the rectum anteriorly. The meningocele is apt to expand with crying or coughing because of its communication with the spinal canal, and pressure on it may cause bulging of the anterior fontanel. The rare anterior spina bifida associated with an anterior sacral meningocele must also be differentiated from a teratoma. Dermoid cysts usually have cavities lined with squamous epithelium and contain associated ectodermal structures such as hair and sebaceous glands. Teratomas are more complex, containing teeth, bone, fat, cartilage, muscle and nerve tissue in many instances. The signs are usually those of a visible mass, pressure, inflammation or purulent discharge. Spontaneous rupture and discharge of the teratoid contents into the rectum may occur. Though the prognosis has been poor, recovery can be expected in most instances when the tumor is removed early in the newborn period.

Sacroccygeal chordomas or chordoblastomas arise from remnants of the primitive notochord and are ectodermal in origin; they are more commonly noted in later life. They are classified as bone tumors, owing to the commonly associated pain from destruction of bone. Pain, sphincter impairment, paralysis and paresthesia are common symptoms. The tumor is usually palpable through the rectum. Destruction of bone as revealed on the roentgenogram is a diagnostic feature. The tumor extends by infiltration, rarely by metastases, but cures are rare.

The neurogenic group includes ependymomas, neurofibromas, neuroblastomas and ganglioneuromas, all of which may occur in the presacral area; lipomas, fibrosarcomas and lymphangiomas are rarely found in this area.

## PERITONEUM AND ALLIED STRUCTURES

### MALFORMATIONS OF THE PERITONEUM

Congenital peritoneal bands at times may be responsible for intestinal obstruction (p. 664); numerous other anomalies may occur in the course of the development of the peritoneum, but are rarely of clinical importance. Intra-abdominal herniations infrequently occur through ringlike formations produced by anomalous peritoneal bands. Absence of the omentum or duplications of it are rare anomalies.

### ASCITES

**Etiology.** The term "ascites" indicates an accumulation of fluid in the peritoneal cavity, but it is usually applied to accumulations of serous fluid. Renal, especially nephrotic, and cardiac conditions are most often responsible for ascites. It may represent a localized and extensive accumulation of fluid in chronic adhesive pericarditis, or it may be part of a polyserositis in so-called Pick's syndrome. Other causes include obstruction of the portal circulation as in hepatic cirrhosis or by enlarged lymph nodes, tumors, thrombosis, chronic tuberculous peritonitis, rheumatic peritonitis or obstruction of the splenic vein.

**Clinical Manifestations.** The abdomen is distended; when the distention is marked, there is flattening or pouting of the umbilicus. Fluctuation can be detected on palpation; a distinct wavelike impulse is obtained by sharp tapping on one side of the abdominal wall while the other hand is placed on the opposite side of the abdomen and an attendant's hand compresses it in the midline; shifting percussion dullness can often be demonstrated.

Ascites must be differentiated from other conditions which cause distention of the abdomen. These include gaseous distention of the intestines, fecal distention as in megacolon, tumor masses, as well as cysts of the mesentery, acute or chronic peritonitis, per-

itoneal hemorrhage from trauma or other causes, extreme distention of the bladder and simple obesity.

**Prognosis and Treatment.** The course, prognosis and treatment depend entirely upon the cause.

### CHYLOUS ASCITES

Chylous ascites is an uncommon form of ascites which may occur at any age of childhood and is occasionally congenital in origin. True chylous ascites is caused by some anomaly, injury or obstruction of the thoracic duct. In the case of anomalies the condition is present at birth or shortly thereafter. At times in traumatic cases there is an associated chylothorax. Obstructions may be produced by enlarged lymph nodes or neoplasms.

The fluid has the appearance of milk, owing to its high fat content. In chronic tuberculous or nontuberculous peritonitis, peritoneal fluid may have a somewhat similar color from degeneration of inflammatory products. The prognosis in chylous ascites is unfavorable, but recovery has followed surgical therapy. The amount of chyle formation can apparently be reduced by decreasing the dietary intake of fat. Since there is a loss of considerable protein in this fluid, high protein diets should be prescribed.

### PERITONITIS

Acute infections of the peritoneum are arbitrarily designated as primary when the focus is outside the abdominal cavity and the infection is blood-borne or lymph-borne. The infection is termed secondary when it is disseminated by extension from or rupture of

an intra-abdominal viscus or of an abscess of one of the solid organs.

Peritonitis in the neonatal period (p. 344) may arise from a transplacental infection in utero; more frequently it is the result of infection acquired during or shortly after birth. It may be a manifestation of septicemia, a direct extension from an umbilical infection, perforation of the intestine or, rarely, the sequel of a ruptured appendix. Meconium peritonitis is described on page 332. After the neonatal period, peritonitis is uncommon until later childhood, when appendicitis becomes relatively frequent.

#### ACUTE PRIMARY PERITONITIS

**Etiology.** Primary peritonitis, which is now relatively uncommon, is most often caused by the *Pneumococcus* and beta hemolytic *Streptococcus*. Streptococcal peritonitis is especially likely to be associated with acute throat infections, scarlet fever and erysipelas; pneumococcal, with throat infections, pneumonia or empyema. Primary peritonitis is more common in girls than in boys, and in some instances a preceding nongonorrheal vaginitis appears to be a portal of entry. Pneumococcal peritonitis is a relatively frequent complication of nephrosis (p. 1046); in such instances the same strain of *Pneumococcus* is frequently isolated from the nose and throat as from the peritoneal exudate. Gonococcal peritonitis is a rare complication of gonorrheal vaginitis.

**Pathology.** The infection is usually widely distributed, although occasionally it is localized in one or more areas. The exudate, which is initially serous or serofibrinous, may become purulent; large amounts of fibrin are formed, especially in pneumococcal infections, and adhesions mat the intestines and other organs together, so that single or multiple localized abscesses may form.

**Clinical Manifestations.** The onset is usually rapid with extreme prostration, some abdominal pain and vomiting. Paradoxically, intestinal activity is usually continued, and diarrhea is common. Evidences of active or subsiding infection elsewhere are often present. The facial expression is likely to be anxious; there is often cyanosis, and the child appears toxic and weak. The temperature is usually septic in type, and may be as high as 104° to 105° F., although in very ill patients, and especially in young infants, it may be normal or subnormal. The pulse is rapid, small and compressible, and the respirations are rapid and shallow because of the pain which abdominal respiration produces.

There is usually distention of the abdomen, moderate diffuse tenderness and a doughy resistance, the latter two being much less than might be expected. Peristalsis is usually active until late in the disease. Evidences of free fluid may be present. Rectal examination reveals tenderness. The white blood cell count is high, ranging from 20,000 to 35,000 with 90 to 95 per cent polymorphonuclear cells with an increase in immature forms. Pus obtained by abdominal aspiration establishes the diagnosis; the procedure is not without risk.

**Prognosis.** Before sulfonamides and antibiotics were available the mortality rate was 80 to 90 per cent; with early treatment recovery is now the rule. Infrequently there is a residual chronic peritonitis.

**Treatment.** Early pelvic drainage with peritoneal lavage with saline solution and antibiotics should be instituted through an abdominal muscle-splitting incision made under local anesthesia. Drainage is facilitated by use of the Babcock type of metal "sump" drain. The general treatment is a modification of the Ochsner method (see treatment of secondary peritonitis, p. 688). Appropriate antibacterial therapy determined by bacterial culture and susceptibility tests should be administered in full dosage and continued for five or six days after apparent recovery. Careful attention to water and electrolyte balance is essential.

#### ACUTE SECONDARY DIFFUSE PERITONITIS

**Etiology.** This type of peritonitis results from perforation of an abdominal viscus or from an abscess of an intra-abdominal organ. Since peptic ulcer, cholecystitis, diverticulitis and pancreatitis are extremely rare in childhood, perforation of the appendix and traumatic rupture of viscera are responsible for the majority of infections. Thus the invading bacteria are largely coliform bacilli with varying numbers of other organisms which, in the main, belong to the streptococcal and staphylococcal groups. Rarely an empyema perforates the diaphragm and is responsible for peritonitis. Strangulation of the intestine as in a hernia or in intussusception is an occasional cause.

**Pathology.** The peritoneal surfaces are lusterless and hyperemic, and the cavity contains cloudy fluid or purulent exudate. Fibrinous adhesions are present between the abdominal viscera, and one or more localized abscesses may result. The larger abscesses, in order of frequency, are located in the pelvic,

the subhepatic and subphrenic areas. Such abscesses may rarely burrow through the abdominal wall, through the diaphragm into the pleura or, more commonly, into a loop of intestine. More often they spread to other peritoneal areas, producing extension of the infection. By lymphatic transmission the subphrenic infections may pass through the diaphragm without actual perforation and produce first a sterile effusion and later an empyema. Pelvic collections of pus irritate the bladder or rectum or both, producing symptoms referable to them.

**Clinical Manifestations.** The manifestations of shock from a ruptured viscus or the early symptoms of acute appendicitis are superseded by an increasing toxemia, as evidenced by greater restlessness and irritability, by a higher temperature, often  $103^{\circ}$  to  $105^{\circ}$  F., by an increase in the pulse rate and, at times, by chills or convulsions. Vomiting, if previously present, is usually increased, the vomitus becoming greenish, then yellowish and finally malodorous, especially if fluids are being taken orally. The pain becomes more diffuse over the abdomen, but may not be too notable if the patient remains quiet, since movement increases it. Constipation is marked, and there is usually no response to *ill advised* suppositories or enemas.

The earliest sign, often present before subjective symptoms, is an increased area of abdominal tenderness and muscular resistance. Rebound pain on sudden release of pressure is indicative of peritoneal irritation, and this too becomes more diffuse. Peristalsis is usually absent unless laxatives or foods have been taken. Later, free peritoneal fluid may be demonstrable by percussion, and some distention occurs. By this time duskeness or cyanosis is usually evident, and apathy or delirium appears.

Rectal examination reveals diffuse tenderness because of the irritation of the pelvic peritoneum. The white blood cell count is usually 16,000 to 25,000 per cubic millimeter, the polymorphonuclear elements being above 90 per cent and immature forms increasing. As the disease advances, the white blood cell count often decreases.

**Treatment.** Of great importance in reducing mortality is a period of preoperative preparation, usually of six to eight hours. Adequate hydration (see p. 195), gastric suction and antimicrobial therapy parenterally are urgently required. Relief of pain by Demerol, morphine or codeine also contributes to improvement. The pulse rate should

be reduced below 120 and the temperature below  $102^{\circ}$  F. if possible. Severely ill patients may require mild hypothermia.

Only when the foregoing has been accomplished is it safe to operate for removal or repair of the viscus producing the infection. Morbidity and mortality may be decreased by aspiration of the peritoneal contents, breaking up of localized abscesses, and repeated lavage of the entire peritoneal cavity with saline solution containing one million units of penicillin and 1 gm. of streptomycin per 500 ml., finally leaving 100 to 200 ml. in the peritoneal cavity as the abdomen is closed. Drainage is best omitted after lavage unless a nonreactive Babcock metal "sump" drain is available. The tube should be introduced into the pelvis and removed as soon as serum only appears in the collection bottle.

Postoperatively the modified Ochsner treatment is effective. It consists of (1) Fowler position, (2) constant gastric suction, (3) nothing by mouth except saline (or water) which is withdrawn by gastric tube, (4) no peristaltic stimulants such as enemas, Prostigmin or Urecholine, (5) Demerol, morphine or codeine for restlessness, and (6) the maintenance of nutrition and fluid and electrolyte balance by parenteral routes. Adequate amounts of vitamins B and C should be given parenterally, and *small* daily transfusions may assist in combating infection by supplying complement. Penicillin and streptomycin or broad-spectrum antibiotics should be continued parenterally; bacterial cultures and sensitivity studies are helpful in selecting appropriate antibacterial agents.

This regimen should be maintained until symptoms have disappeared and peristalsis is effective in passing gas per rectum. Then enemas and increasing diet may be permitted after withdrawal of the gastric tube.

**Prognosis.** Owing to improvements in treatment, the case fatality rate has decreased to approximately 1 per cent.

#### ACUTE SECONDARY LOCALIZED PERITONITIS

##### (ABSCESS)

**Etiology.** A single, localized pyogenic abscess, which most often is secondary to a perforation of an inflamed appendix, is somewhat less common in children than in adults. The poor ability of young children to localize a peritoneal infection of appendiceal origin has been attributed to a lower order of resistance and to a relatively smaller omen-

tum. Though localized peritoneal abscesses occur most often in the appendiceal region, they may be at any site, originating from various sources, or appendiceal infections may gravitate to other areas, notably the pelvic. An abscess in the subdiaphragmatic area may originate from an appendiceal or other intra-abdominal infection or, rarely, from an empyema. Appendiceal abscesses may result from perforation of the appendix, contamination of the region at the time of operation or failure to drain a contaminated area. Multiple abscesses may be part of a diffuse peritonitis, resulting from the matting together of loops of intestines and other abdominal viscera by adhesions.

**Clinical Manifestations.** The general symptoms of peritoneal abscess are continued fever or recurrences of it, poor appetite, and vomiting upon the ingestion of food. The white blood cell count is increased, with a predominance of polymorphonuclear cells. In addition, peritoneal abscesses may produce more or less characteristic manifestations dependent upon their location.

In the appendiceal area, tenderness in the right lower quadrant is extended, and there is often a palpable mass.

A pelvic abscess is suggested by abdominal distention, rectal tenesmus with or without the passage of small stools containing mucus, or bladder irritability. Rectal examination reveals a bulging tender mass anteriorly which impinges on the rectal lumen.

A subphrenic abscess is evidenced by physical signs at the base of the lung, usually the right, due to elevation of the diaphragm, and frequently by the presence of pleural fluid. The diagnosis can often be established roentgenographically. The diaphragm is elevated and the liver depressed if the infection is on the right side, and there is frequently a pocket of air just below the diaphragm, owing to production of gas by bacteria.

**Treatment.** General treatment of peritoneal abscesses consists in maintenance of fluid and nutritive requirements by parenteral routes, if necessary, and in broad-spectrum antibiotic therapy. Adequate drainage remains the best method of treatment. Pelvic abscesses are preferably drained into the rectum through its anterior wall. A subphrenic abscess can be approached through the bed of the resected twelfth rib. If there is an associated empyema, the tenth or eleventh rib is resected rather than the twelfth, and each infection can be drained through the same

incision, with a tube directed into each cavity.

The appendix should be removed if easily accessible. Otherwise it should be removed after infection has subsided.

#### CHRONIC NONTUBERCULOUS PERITONITIS

**Etiology.** Chronic infections of the peritoneum, the majority of which are caused by tuberculosis, are relatively uncommon. There is a wide variety of etiologic agents. A chronic, localized purulent peritonitis may follow an acute infection, and occasionally there is a chronic diffuse involvement. In other instances localized or widespread adhesions remain after the infection itself has been controlled. Fetal peritonitis may have become chronic by the time of birth, or there may be adhesions without evidence of active infection. Pick's syndrome or a polyserositis involving the pericardium, pleura and peritoneum, often attributed to tuberculosis, may apparently be caused by other agents. Non-purulent peritoneal involvement is occasionally seen in children with active rheumatic fever, and there may be an etiologic relationship. Actinomycosis, although not primary in the peritoneal cavity, may be responsible for chronic indolent infections of it.

Tuberculous peritonitis (see p. 468).

#### TUMORS OF THE PERITONEUM AND MESENTERY

*Mesenteric cysts* are commonly lymphatic in type (lymphangioma, p. 1359) and probably are malformations rather than true neoplasms. They may be responsible for abdominal pain, constipation, intestinal obstruction or simply large intra-abdominal masses which must be differentiated from the various intra-abdominal neoplasms; large mesenteric cysts may simulate ascites. The treatment is surgical removal. Other cystic malformations or neoplasms involving the mesentery include

duplications of the gastrointestinal tract, dermoid cysts and teratomas. Primary neoplasms of the peritoneum are exceedingly rare; we have observed one example of a mesothelioma in an inguinal hernial sac in a child. Lymphosarcoma may be primary in the stomach, small intestine or the mesenteric lymph nodes. A variety of other mesenchymal neoplasms may occur in the mesentery.

## HERNIA AND HYDROCELE

Hernias of various types may be present at birth or develop subsequently, often because of congenital defects. The uncommon femoral hernia and the rare internal hernias other than that of the diaphragm will not be discussed. Congenital omphalocele and umbilical hernia are discussed on page 340.

### INGUINAL HERNIA

**Etiology and Pathology.** Most inguinal hernias are of the indirect rather than the direct type and occur much more frequently in boys than in girls. The hernia may be present at birth or may appear at any age thereafter; it is situated more often on the right side than on the left, but frequently is bilateral.

During embryonic life, as the testis descends retroperitoneally from the genital ridge, a sac of peritoneum (the processus vaginalis) precedes it into the scrotum. The lower portion of this sac envelops the testis to form the tunica vaginalis, and the remainder normally atrophies by the time of birth. The indirect inguinal hernia results from a persistence of the processus vaginalis and becomes manifest as a mass in the inguinal region when an abdominal structure or peritoneal fluid is forced into it. The persistent sac may vary from a short one not extending beyond the external inguinal ring to one which extends into the scrotum and maintains its continuity with the tunica vaginalis. The hernial sac is thus present at birth, but it usually remains empty for a variable period of time. At a later date, commonly by two or three months of age, when the infant becomes more active and is able to increase his intra-abdominal pressure sufficiently to open the sac, peritoneal fluid or an abdominal organ is forced into it. It then appears as a bulge in the inguinal region, extending into the scrotum or toward the labia, depending on the length of the peritoneal sac which it enters.

**Clinical Manifestations.** There are no

symptoms associated with an empty hernial sac. When abdominal contents are intermittently forced into it, symptoms of incomplete bowel obstruction with pain, fretfulness, difficult defecation, poor eating and local pressure may result. However, there may be few or no symptoms associated with a filled hernial sac. If a loop of intestine becomes incarcerated in the sac, there may be all the manifestations of intestinal obstruction ultimately leading to strangulation of the bowel and death. In female infants the ovary may prolapse into the hernial sac and appear as a 1- to 2-cm. movable, nontender, usually transient inguinal mass. Immediate surgical exploration and oophorectomy are required if strangulation occurs. Occasionally the neck of the sac becomes twisted after peritoneal fluid has been forced into it and traps the fluid as an encysted, nontender irreducible hydrocele in the cord in the male or in the canal of Nuck in the female.

**Diagnosis.** A history of the intermittent appearance of a mass in the inguinal region of an infant or child is characteristic. If the hernial sac is full at the time of examination and can be emptied by gentle compression or if it can be made to fill when the infant cries or strains or the older child stands or coughs, the diagnosis is established. Often, however, a suggestive history is the only criterion for diagnosis. Inspection may reveal a fullness on the affected side, especially following recent incarceration. Palpation for an enlarged internal ring by invaginating the scrotum is fruitless during the early developmental stage of the hernia, since the ring is not enlarged, nor are the muscles weakened. However, gentle palpation by rolling a finger over the spermatic cord at the level of the pubic tubercle will reveal thickening of the cord on the involved side, and often the "silk glove" sensation may be elicited by the rubbing together of the two sides of the empty hernial sac. This maneuver should be performed as part of routine physical examinations in infants in order to discover the presence of a hernial sac so that it can be removed before incarceration occurs.

The only difficulty in diagnosis is in distinguishing hernia from hydrocele. A hernial sac is often opaque to transmitted light, whereas the hydrocele is translucent. A hernia, however, may also be translucent if only distended and empty bowel is present in the sac. The inguinal hernia is usually reducible with gentle manipulation and tends to slip suddenly into the peritoneal cavity.

By contrast, the encysted hydrocele is not reducible, and, although the communicating one is, it is usually accomplished by manipulation only with great difficulty and without sudden emptying of the sac. Characteristically it is reduced most readily while in the horizontal position for a prolonged time as during a night's sleep. The coexistence of a communicating hydrocele and an inguinal hernia is relatively common.

**Treatment.** The treatment of inguinal hernias in healthy infants and children is by surgical repair as soon as the defect is diagnosed. If there is a suggestive thickening or a "silk glove" feeling on the opposite side, bilateral exploration is recommended. The operation consists essentially in removing the hernial sac and transfixing the neck at the internal ring. It is well tolerated by even small infants and obviates the possibilities of incarceration, testicular atrophy, secondary enlargement of the internal ring and weakening of the floor of the canal from prolonged pressure. Treatment by injection of sclerosing agents is contraindicated in infants and children.

Trusses are not recommended, except rarely for temporary use. They are difficult to apply correctly, impossible to keep clean, may cause testicular atrophy from pressure, and do not cause the hernial sac to obliterate permanently. When operation must be deferred and it seems desirable to avoid protrusion of the hernia, a yarn truss or the type described by Potts may be used temporarily. The latter consists of a small triangular cotton pad held in place over the inguinal ring by a T binder or belt made of gum rubber. It has the advantage that the small cotton pads, which are buttoned on, can be easily replaced when soiled.

**Incarcerated inguinal hernia.** Incarceration of inguinal hernias is common in children (20 per cent have a history of it) and occurs most often in the first six months of life. It is manifest by the appearance of a firm, tender, globular, irreducible swelling below the external inguinal ring. The infant is fretful and often vomits. Unless relieved, abdominal distention, cessation of bowel movements, persistent vomiting, fever and leukocytosis will develop as impairment of the blood supply progresses.

Manipulative reduction of an incarcerated hernia which has been present for less than twelve hours and has not been accompanied by a bloody stool is the treatment of choice. The infant is adequately sedated (with a

barbiturate under six months of age or with morphine in an older patient). He is then placed in the Trendelenburg position with a roll of cloth under the buttocks, and an ice bag is placed on the affected side to decrease the edema. After an hour or more when the sedation has taken effect and the parents have quieted the infant to sleep, the mass is gently grasped with all fingers of the physician's warmed hand and squeezed with gentle equal pressure by all digits toward the inguinal canal. This maneuver frequently leads to reduction. The patient should then be observed closely for several hours for signs of peritoneal irritation to make certain that non-viable bowel has not been reduced. During the next several days the infant's metabolic upset is corrected, and the edema in the hernial sac is permitted to subside; elective herniorrhaphy is then performed.

If the incarcerated hernia cannot be reduced or if it is inadvisable to attempt it because of its duration, emergency surgical correction must be undertaken, with provisions available for bowel resection if it is necessary.

#### HYDROCELE

A hydrocele is the presence of fluid anywhere along the course of the processus vaginalis.

Newborn male infants whose processus vaginalis has obliterated frequently have residual peritoneal fluid in the tunica vaginalis of the testis. This common type of *non-communicating hydrocele* forms an oval, fluctuant, tense, translucent sac, and the spermatic cord and ring can usually be felt above it. The fluid gradually absorbs during the first year of life, and surgical correction is rarely required.

If the processus vaginalis remains open, peritoneal fluid may be forced into it, forming a hydrocele of the spermatic cord or of the canal of Nuck in the female. An inguinal hernia is often associated. Frequently the parents note that the "testis seems larger" in the evening after an active day, and smaller the following morning. This history is highly suggestive of the *communicating hydrocele* (see Diagnosis under Inguinal Hernia). The length of the hydrocele is dependent upon the extent of the patency of the processus vaginalis. If it extends into the tunica vaginalis, then the elongated fluctuant mass extends to the lower part of the scrotum. When the occlusion is at a higher level, the hydrocele is a fluctuant swelling above the scrotum or extending only a short way into it.

FIG. 201. Congenital diaphragmatic hernia. A, Film exposed shortly after birth: distortion of shadow of left leaf of diaphragm, with huge, masslike density in left chest displacing heart to right. B, Film exposed about 20 minutes after A. As the result of swallowed air, coils of air-filled small bowel are now demonstrated in the left chest. The esophagus is outlined by swallowed contrast material. Operative correction was attempted because of extreme dyspnea. Infant died  $5\frac{1}{2}$  hours after birth.

Occasionally the fluid becomes trapped in the sac and forms a firm globular mass which is irreducible and resembles an incarcerated inguinal hernia. If the fluid is at some distance below the external inguinal ring or has been present for several days and is neither tender nor symptomatic, the diagnosis of a hydrocele may safely be made. The sudden appearance of an irreducible hydrocele near the external ring is usually impossible to differentiate from an incarcerated hernia. Transillumination is of no value in such a case, since an incarcerated intestine will also transmit light before it becomes hemorrhagic. Emergency surgical exploration may be necessary for differentiation.

Since the appearance of a hydrocele some time after birth is evidence of a persistent processus vaginalis, the hydrocele should be extirpated by the inguinal route and the hernial sac removed. Aspiration of the tunica vaginalis or injection of sclerosing solutions is not warranted; either one may cause ad-

hesions, which makes the ultimate operation more difficult and may damage the testis.

#### EPIGASTRIC HERNIA

Epigastric hernias occur in the midline between the umbilicus and the lower end of the sternum. They are not common and, except for their location, are similar to umbilical hernias. They should be repaired surgically.

#### INCISIONAL HERNIA

Postoperative hernias should be repaired as soon as the local condition of the wound and the general condition of the child warrant it. There is no justification for permitting children to continue with the discomfort attendant on this type of hernia.

#### DIAPHRAGMATIC HERNIA

**Etiology.** Diaphragmatic hernia may be congenital or acquired. In the former there may be no diaphragmatic tissue at the position of the opening, or the hernia may occur

through the esophageal hiatus (p. 642), the canal of Bochdalek or the foramen of Morgagni. It occurs more frequently on the left than on the right side. Diaphragmatic eventration is, strictly speaking, not a hernia, but somewhat similar in effect, since abdominal viscera displace thoracic structures because of the weakness and ballooning of half of the diaphragm. In some instances eventration occurs in infants born by breech delivery who have received an injury to the phrenic nerve alone, or in association with one of the brachial plexuses. Acquired diaphragmatic hernias are usually traumatic in origin.

**Pathology.** There are all degrees of protrusion of the abdominal viscera through the diaphragmatic opening into the thoracic cavity. In extensive cases the stomach and a large part of the intestines displace the lungs and heart, and there may be an abnormal depression of the abdominal wall. There may be an associated incomplete rotation of the cecum and, at times, duodenal constricting bands. The lung on the affected side is often hypoplastic, and hypoplasia of the opposite lung has also been observed.

**Diagnosis.** There may be no symptoms, and the condition may be discovered only by chance roentgenographic examination. On the other hand, there may be symptoms of severe respiratory distress present from birth, including dyspnea and cyanosis; there may also be persistent vomiting and other evidences of intestinal obstruction. When symptoms are not present at birth, they may appear at any time and include such digestive disturbances as discomfort after eating, severe colicky pain, vomiting and constipation. Acute intestinal

obstruction is always a possibility in these cases.

The physical examination varies considerably. The percussion note over the part of the thorax containing the stomach and intestines may be more tympanitic or duller than usual, and the respiratory murmur absent, decreased or increased, in either case; at times the sounds of intestinal peristaltic movements can be heard over the chest. The diagnosis can usually be established by roentgenographic examination, often without the aid of a contrast medium; but when there is any doubt about abnormal intrathoracic masses, examination after ingestion of a contrast material other than barium should be made to determine whether the "mass" consists of stomach and intestines.

The *symptoms* of traumatic hernia may be obscured by those of other injuries, but are usually dyspnea, cyanosis and shock.

**Treatment.** This is surgical. When there are acute symptoms, the procedure is an emergency and there is considerable risk. When there are no symptoms or only intermittent ones, operation is elective, but should be performed as early as possible.

## THE LIVER

**Anatomy.** The liver of the full term infant weighs 120 to 160 gm. at birth. The weight is doubled at two years and tripled at three years; at nine years it has increased six times, and at puberty, ten times. The liver of the adult is twelve to thirteen times as large as that of the newborn infant. The relative sizes of the lobes of the liver change with age; at birth the right lobe is twice as large as the left lobe; in young children and adolescents it is about three times as large. The functional right and left lobes, drained by the right and left hepatic ducts and supplied with corresponding portal venous branches and hepatic

veins, differ from the anatomic lobes. The anterior surface of the liver is gradually roofed over by the ribs and diaphragm. In the newborn infant the liver edge is usually less than 2 cm. below the costal margin in the right midclavicular line. The upper border of hepatic dullness is at the level of the fifth or sixth rib in the mammary line and extends nearly horizontally. In the axillary line it is usually in the seventh intercostal space and posteriorly in the ninth space. The lower border of the liver may be normally palpable about 1 cm. below the subcostal margin throughout childhood.

\* In the intestinal tract only stercobilinogen is produced by bacterial reduction of bilirubin. Urobilinogen is produced by cellular enzymatic activity in the liver and biliary passages and does not normally appear in the urine; under physiologic conditions only stercobilinogen and stercobilin appear in the urine.

FIG. 202. Metabolism of hemoglobin and bile pigments.

The lobules are not clearly demarcated at birth. They increase in size with age, and almost the entire growth of the liver is due to increase in their size. Extramedullary hematopoiesis, varying inversely in amount with the birth weight, may be found normally in the liver of infants for a few weeks after birth.

**Congenital Anomalies and Malpositions.** Absence of the liver has been reported in still-born fetuses in association with other severe anomalies. The lobes of the liver may vary in size and shape; either one may be absent, or there may be more than two. Riedel's lobe is the tongue-like downward projection of the

right lobe. A "floating liver" occurs when there is congenital elongation of the ligaments which support the organ. In situs inversus the liver is on the left side; with diaphragmatic hernia it may be located in the thorax.

Downward displacement of the liver is produced by contractural deformities of the thorax (rickets), relaxation of the abdominal musculature (severe malnutrition, amyotonia congenita and other paralyses) or increased intrathoracic pressure (empyema, pneumothorax or emphysema). Subphrenic abscess or a collection of air (perforation of the gastrointestinal tract) will push the liver down-

ward. The less common upward displacement of the liver may be caused by ascites, abdominal tumors or paralysis of the diaphragm.

**Physiology.** The liver has multiple and complex physiologic functions. It secretes bile and takes an important part in metabolism, blood formation, and detoxification.

**Bile.** The important biliary constituents are the bile salts, the bile pigments, cholesterol and lecithin. The bile salts, made solely by the liver cells, are excreted into the intestine, reabsorbed and returned to the liver by the portal blood stream for re-excretion.

Bile pigments are formed by the entire reticuloendothelial system. It is estimated that the reticuloendothelial cells of the liver (Kupffer's cells) make only a minor portion of the bilirubin excreted.

Bile pigment is formed chiefly from hemoglobin, but myoglobin and possibly the enzymes containing heme pigment (catalases, peroxidases, cytochromes) may also be degraded to bilirubin. After phagocytosis, hemoglobin is transformed by coupled oxidation-reduction reactions to a green compound, *choleglobin* (verdoglobin). The globin moiety is enzymatically digested and enters the protein pool of the body; iron is released from heme and is stored in the liver; the remaining porphyrin ring is split into an open chain tetrapyrrole compound, biliverdin, which is reduced to bilirubin. Excreted into the blood, bilirubin is bound by albumin and carried to the liver cells, where it is conjugated with glucuronide and excreted into the bile. The enzymes, glucuronyl transferase and uridine diphosphate-glucuronic acid dehydrogenase, are involved in this conjugation (Fig. 203).

In the intestinal tract, bilirubin is reduced to stercobilinogen by bacterial action and is excreted in part in the stools in its oxidized form, stercobilin. If it escapes oxidation, e.g., during the ingestion of antibiotics, bilirubin auto-oxidizes to biliverdin and imparts a green color to the stools. Part of the stercobilinogen is reabsorbed into the portal circulation, carried to the liver and almost entirely excreted in the bile, forming the so-called *enterohepatic circulation of bile pigments*. Stercobilinogen, which gets into the general circulation, is

excreted by the kidney as urobilinogen; it is quickly oxidized to urobilin after the urine has been passed. Stercobilinogen is in part further decomposed in the intestines to mesobilileukan (pro-mesobilifuscin), a dipyrrole compound, which is rapidly polymerized to mesobilifuscin (or coprochrome) and is responsible for some of the brown color of feces. It is possible that the pigment of the urine, urochrome, is bilifuscin, a derivative of coprochrome.

The average normal fecal excretion of urobilinogen is 3.9 mg. a day for infants under one year of age; this increases with age to a level of 45.5 mg. by ten to fourteen years of age. When the liver is unable to excrete all the stercobilinogen brought to it by the portal circulation, abnormal amounts appear in the general circulation and in turn are excreted in the urine. This may occur with excessive hemolysis or when there is extensive disease of the liver.

The porphyrins are another series of pigments related to hemoglobin, differing from the bile pigments in that the porphyrin ring is not split open. Porphyrins are present in the stool, presumably excreted by the bile, and in the urine. Other than their association with the various clinical types of porphyria, little is known of their normal physiology during infancy and childhood. Their metabolism is disturbed in various forms of hepatic disease; the retention of porphyrins in hepatic failure may be connected with the cerebral dysfunction of hepatic coma.

Phosphatase is excreted in the bile. Whether the elevated serum phosphatase of obstructive jaundice is due to failure of biliary excretion or to excessive release from injured hepatic cells is not known.

**Metabolic functions.** Owing to its important role in the metabolism of the various foodstuffs, the liver has been aptly termed the commissariat of the body.

The liver plays the leading role in maintenance of the normal blood sugar level. It forms and stores glycogen from glucose, levulose, galactose and dextrolactate. It converts the glycogenic amino acids and the glycerol fraction of fats into dextrose, which is de-

FIG. 203. Enzymatic steps in glucuronide synthesis. UDP = uridine-diphosphate; DPN = diphosphopyridine-nucleotide. (Modified from Brown and Zuelzer: J. Clin. Invest., Vol. 37.)

posited as glycogen (glycogenesis). Glycogen can be reconverted into glucose by the liver (glycogenolysis). Thus the liver serves as a storehouse of readily available glucose which can be delivered to the blood when required. The livers of young infants contain proportionately less glycogen than those of older children.

The liver is the site of both synthesis and oxidation of fat. Hepatic lipogenesis from acetate and pyruvate depends upon the normal functioning of both the anaerobic glycolytic (Embden-Meyerhof) and phosphoglucuronate pathways of carbohydrate metabolism. Most, if not all, of the fat mobilized in the liver is combined with lecithin and changed to phospholipid, a change which is apparently necessary for its transport and subsequent use. Dietary deficiency of lipotropic factors (e.g., choline, inositol or compounds which can contribute methyl groups for the formation of choline) prevents the formation of the more soluble phospholipid, so that fat accumulates in the liver. Cholesterol is formed in the liver from its esters or by synthesis from acetic acid. Cholesterol esters, i.e., compounds of cholesterol and fatty acids, which constitute 70 per cent of the plasma cholesterol, are also formed in the liver and are a means for the rapid transport of cholesterol. The plasma lipoproteins which transport triglycerides also appear to be, in part, formed in the liver.

The liver (and kidney) breaks down long-chain fatty acids into ketone bodies, which are burned by and supply energy to the muscles and other tissues which cannot form them. When fat is burned in excess (starvation and diabetes), the large amounts of ketone bodies produced appear in the blood and urine. The formation of ketones is an incompletely developed function in young infants (Heymann).

Urea is formed exclusively in the liver by the deamination of amino acids; it is apparently a waste product of the conversion of glucogenic amino acids to glycogen. The liver is concerned with the formation of many fractions of the serum proteins.\* Fibrinogen, a globulin, is formed exclusively in the liver. Prothrombin and other coagulation factors and probably all the serum albumins are of hepatic origin. The liver also serves as a

storage depot for protein. There is a large labile fraction of the hepatic proteins which increases with a high protein diet and decreases during starvation. In many disease states of the liver there is an increased concentration of serum globulins.

Vitamins A, C and D are stored in the liver, and considerable amounts of A and D remain for a long time after the administration of single large doses. The precursors of vitamin A are converted into vitamin A in the liver. The damaged liver has a reduced storage capacity for vitamin A and a lowered capacity for the conversion of its precursors. Riboflavin and vitamins E and K have important metabolic storage relationships to the liver.

**INFLUENCE OF DIET UPON THE LIVER.** The vulnerability of the liver to toxic agents may be reduced or eliminated by various dietary constituents. A high carbohydrate diet has a protective action for the liver. This has been attributed to the resultant increased glycogen content of the liver, but may be due to other factors, since the young infant with a low hepatic glycogen content is more resistant than the adult to a hepatic poison such as carbon tetrachloride. An adequate protein intake also shields the liver from toxic injury; *methionine* and *cystine* are recognized as some of the protective elements in protein.

Dietary deficiencies lead to hepatic injury. A low protein diet results in massive hepatic necrosis, specifically as a result of cystine deficiency. Absence of tocopherol from the diet also predisposes to this type of liver damage. Protein deficiency of lesser degree or a high fat diet produces fatty infiltration of the liver which slowly progresses to diffuse hepatic fibrosis. This sequence of hepatic injury may be prevented by the inclusion of choline or methionine in the diet, both of which tend to prevent fatty infiltration of the liver.

**Blood formation.** In the fetus the liver is an active site of blood formation. Hematopoiesis is common in the livers of premature and occasionally of full term infants as a remnant of this fetal function. In conditions such as hemolytic anemias in which excessive demands are placed on the blood-forming mechanisms the liver undergoes myeloid metaplasia and resumes its hematopoietic activity. The liver also serves as a storehouse for iron during the early months of infancy and is used when the infant's diet is chiefly milk and is low in iron. With depletion of this store by about the fifth

\* A case reported by Thompson, McQuarrie and Bell emphasizes the role of the liver in the formation of the serum proteins. In a child with generalized edema and hypoproteinemia the sole finding at autopsy was an idiopathic atrophy of the hepatic cells.

month, hypochromic anemia develops if the diet is not planned to contain foodstuffs with a high iron content.

**Detoxifying functions.** The liver can alter various exogenous toxic substances by conjugating them with sulfuric acid, glucuronic acid (an oxidation product of glucose) or amino acids. The conjugation mechanism is probably more concerned with increasing the solubility of the toxic substance so that it can be more easily transported through the body

fluids and excreted than it is with a direct reduction in toxicity. Thus sulfanilamide is converted into the more soluble but more toxic compound, acetyl sulfanilamide. The liver also appears to be the principal site for removal of ammonia from the blood. The natural and synthetic estrogenic and androgenic substances are inactivated by the liver. Excess of these hormones in the body, when the damaged liver fails to dispose of them, results in abnormal physiologic effects.

## TESTS OF LIVER DISTURBANCES AND FUNCTION

Since there is no test which specifically detects active parenchymal hepatic disease, laboratory tests have their greatest usefulness in the presence of clinically obvious liver disease by supplying some measure of the progress of the disease—information that is of assistance in prognosis and management. They are helpful in differentiation of the various types of jaundice and in detection of hepatic derangement in nonicteric patients.

Tests utilized to study liver disease may be divided into two main classes, depending upon whether they do or do not measure liver function.

### TESTS NOT MEASURING DERANGEMENT OF LIVER FUNCTION

A large group of tests do not measure any known physiologic function of the liver, but are seemingly dependent upon the presence in the body fluids of some by-product of active liver damage. These tests are at best presumptive indicators of the continued presence of an active pathologic process in the liver.

**Cephalin-Cholesterol Flocculation Test.** This test is based upon the capacity of the serum of patients with active liver disease to flocculate a colloidal cephalin-cholesterol suspension. Alterations in serum albumin and alpha globulin, which normally act as stabilizers of the suspension, are thought to be responsible for flocculation. The test is not specific for liver disease, but provides useful prognostic data. There is often a positive reaction in the newborn infant during the early days of life, which is apparently not due to liver disease; postpartum women also have a positive test for several days.

**Thymol Turbidity Test.** This test is based on the production of turbidity within thirty minutes in a saturated buffered thymol solution by the serum of patients with hepatic disease, largely owing to increases in beta globulin content. The serums of normal persons and of patients with uncomplicated obstructive jaundice produce little or no turbidity.

**Colloidal Gold Reaction of Blood Serum.** This test is based on the changes in stability of colloidal gold suspensions produced by alterations in the globulin and albumin patterns resulting from hepatic damage. The Takata-Ara, formol-gel and Weltmann's coagulation band reaction tests have a similar basis.

**Erythrocyte Sedimentation Rate Test.** This test is as useful in following the course of an active infection of the liver as it is for many other diseases.

**Tyrosinuria and Leucinuria.** The amino acids tyrosine and leucine are present only in traces in normal urine. When present in clinically demonstrable quantities, they indicate autolysis of the liver. Thus in acute yellow atrophy of the liver a high percentage of patients have tyrosine in the blood and urine.

**Coproporphyrin in Urine.** The urinary coproporphyrins are increased in hepatic disease. In acute hepatitis and the cirrhosis following it, coproporphyrin I is increased; in alcoholic cirrhosis, coproporphyrin III is increased. Normally, 20 to 120 gammas of total urinary coproporphyrin are excreted daily by adults.

**Serum Levels of Transaminases.** The levels of serum glutamic-oxaloacetic and glutamic-pyruvic transaminases are elevated when hepatic cells are injured by disease or trauma. These tests are of value diagnostically and in following the clinical course, for example, of hepatitis.

### TESTS MEASURING FUNCTIONAL CAPACITY

The manifold functions of the liver make it obvious that no single test can be depended upon to measure the over-all functional capacity of the liver. The use of a suitably selected test or group of tests repeated periodically, however, may furnish valuable information. The so-called large reserve of functional capacity is stressed as a factor limiting the sensitivity of these tests. This reserve is predicated chiefly upon the fact that after surgical removal of a large part (80 to 95 per cent) of the normal liver there is still adequate hepatic function. It is likely that this reserve may be more illusory than real in the diseased liver, for many hepatotoxic agents can inactivate hepatic metabolic mechanisms without visibly apparent cellular damage. Since most liver function tests measure but a single function of this organ, they may be classified according to the function measured.

### TESTS DEPENDENT UPON THE ROLE OF THE LIVER IN CARBOHYDRATE, PROTEIN AND FAT METABOLISM

#### CARBOHYDRATE TOLERANCE TESTS

These tests furnish an index of the capacity of the liver to convert the monosaccharides, glucose, levulose and galactose, into glycogen (glycogenesis). Liv-

ington and Bridge have standardized these tests for infants under two years of age.

The diet of the patient has an influence on the type of response. A high carbohydrate diet results in a low blood sugar curve, and a high fat diet or starvation causes a high, prolonged curve in the tolerance tests, the so-called starvation diabetes. Accordingly, the patient should be fed a diet of average caloric content which provides about 50 per cent of the calories as carbohydrate for three days preceding any of the carbohydrate tolerance tests. Since frequent repetition of the dextrose tolerance test results in successively flatter tolerance curves, tests should not be repeated at intervals of less than three days. A twelve-hour fast should precede the test for infants receiving four to five feedings daily. A nine-hour fast is adequate for premature infants or for infants receiving six or more feedings daily.

**Glucose Tolerance Tests. Oral.** The following test doses of glucose administered in a 25 per cent solution have been suggested by Bridge and Mulholland:

0-18 months . . . . .	2.50 gm. of glucose/kg.
18 months-3 years . . .	2.00 gm. of glucose/kg.
3-12 years . . . . .	1.75 gm. of glucose/kg.
12 years or older . . . .	1.25 gm. of glucose/kg.

A blood sugar determination is obtained before administration of the sugar (fasting) and subsequently at one-half hour, one hour, two hours and three hours. A rise in venous blood sugar to 140 to 155 mg. per 100 ml. within a half-hour or an hour and a return to a normal level within two to three hours is a normal response. The sugar levels of arterial or capillary blood during the immediate postprandial phase are somewhat higher (20 to 50 mg. per 100 ml.) than are those of venous blood; fasting levels are essentially equal. It must be remembered that other factors, such as poor intestinal absorption (as in celiac disease, intestinal tuberculosis, nephrosis), influence the oral glucose tolerance curve.

**Intravenous glucose tolerance test.** See page 1219.

**Epinephrine Test.** See page 1219.

**Galactose Tolerance Test.** This monosaccharide is probably not utilized by the tissues, but is metabolized almost entirely in the liver. After an oral dose of 1.75 gm. per kilogram of body weight, urine is collected for a period of four hours. If more than 3 gm. of galactose appear in the urine during this time, it is presumed that the liver's capacity to convert galactose to glucose is impaired.

#### TESTS DEPENDENT UPON HEPATIC FAT METABOLISM

**Cholesterol Partition of Blood Plasma.** Normally the ratio of cholesterol esters to free cholesterol is approximately 2:1. A reduction in the amount of esterified cholesterol occurs in patients with liver damage. Since other factors may disturb the amounts of cholesterol esters, a single determination has little value in assessing liver damage.

#### TESTS RELATED TO HEPATIC PROTEIN METABOLISM

**Serum Protein Concentrations.** The total serum proteins are usually reduced in liver disease with a resultant decrease in serum colloid osmotic pressure.

The decrease is almost entirely due to a lowered concentration of serum albumin. The small increases in serum globulin fractions which occur in most liver diseases are also seen in nonhepatic disorders, since they stem from hyperactivity of the reticuloendothelial system. Increased alpha, beta and gamma globulin fractions are in part the causes of the flocculation, precipitation and turbidity in the tests for hepatic injury. A large increase in serum globulin is invariably due to hypergammaglobulinemia.

**Plasma Amino Acid Tolerance Curves.** Spontaneous increase in the plasma level of amino acids is rare and is usually due to amino acids (tyrosine) liberated from autolyzed liver tissue and not to failure of removal of amino acids by the liver. A retention of plasma amino acids occurs in patients with liver disease after their intravenous injection.

**Prothrombin Concentration of the Blood.** The liver plays a dual role in the regulation of the prothrombin level of the blood. Bile salts are necessary for the absorption of vitamin K, a precursor of prothrombin, from the intestinal tract. This factor explains the bleeding tendency of patients with obstructive jaundice. The diseased liver is impaired in its capacity to utilize vitamin K in the formation of prothrombin. Failure to obtain an elevation of a lowered prothrombin time after the parenteral injection of vitamin K is presumptive evidence of impaired liver function.

#### TESTS BASED UPON THE SECRETORY AND EXCRETORY FUNCTIONS

**Bilirubin—The van den Bergh Reaction.** Normally the two forms of bilirubin, the direct (or conjugated) and the indirect (or unmodified) types, are transported in the circulation in loose combination with serum albumin. Direct-reacting bilirubin is conjugated to glucuronic acid; in the plasma it is a mixture of the monoglucuronides and diglucuronides of bilirubin. The total concentration of both types ranges normally from 0.2 to 1.4 mg. per 100 ml., with 0.2 mg. per 100 ml. as the upper limit for the direct type. Since concentrations of bilirubin are often expressed in van den Bergh units per liter, it is to be noted that 1 van den Bergh unit per liter is equivalent to a bilirubin concentration of 5 mg. per liter.

When Ehrlich's diazo reagent (a mixture of sulfanilic acid, hydrochloric acid and sodium nitrite) is added to a solution of bilirubin glucuronide, a reddish violet color (azobilirubin) is produced. The term *direct* is applied to either this type of bilirubin or to the van den Bergh reaction itself when the color develops rapidly in an untreated bilirubin solution. No color results when the diazo reagent is added to a solution of unmodified bilirubin. However, if alcohol is added to the unmodified bilirubin solution, it then reacts with the diazo reagent to produce the reddish violet color. The term *indirect* is thus used for either unmodified bilirubin or the van den Bergh reaction in which alcohol is used as a catalyst to allow the color to develop.

The van den Bergh reaction serves as both a qualitative and quantitative test for bilirubin. Qualitatively, it differentiates the types of bilirubin (conjugated and unmodified). As a quantitative test it is used to measure the total amount of bilirubin or

the separate quantities of conjugated or unmodified bilirubin present in a serum sample. The presence of direct bilirubin is revealed by the prompt development of color when the diazo reagent is added: a photoelectric colorimetric reading of the color intensity after one minute quantitates this type of bilirubin. A photoelectric colorimetric reading taken on an alcohol-treated serum specimen one-half hour after diazotization measures the total bilirubin content. Indirect bilirubin is calculated by subtracting the direct from the total bilirubin content. Qualitatively, the following inferences may be drawn from the van den Bergh reaction: (1) Direct bilirubin as the sole or predominant pigment demonstrable is indicative of obstructive (regurgitation) jaundice. (2) The occurrence of indirect bilirubin in abnormal concentrations signifies a hemolytic (retention) jaundice. (3) Increased amounts of both direct and indirect bilirubin are found in toxic and infectious jaundice in which there is simultaneously retention and regurgitation of bilirubin.

As a quantitative test the van den Bergh reaction is useful in diagnosis and prognosis and in following the course of the disease process.

**Bilirubin clearance rate or removal of injected bilirubin from the blood.** Weech and his co-workers developed a quantitative test which measures the

rate at which the liver removes injected bilirubin from the blood.

**The icteric index.** In this test, which has limited usefulness, the color of the plasma is compared with that of a standard potassium dichromate solution. The color intensity of the standard is taken as unity. Values greater than 9 units are considered indicative of an increase in total serum bilirubin. Carotenemia, turbidity due to lipemia, and hemolyzed samples all result in false readings.

**Urobilin excretion\* (urine and stool).** A study of urobilin excretion aids in differentiating various types of jaundice. In jaundice due to excessive hemolysis there is an increased urinary urobilin, owing to the larger amounts of stercobilinogen formed in the intestine from the excessive bilirubin made available by hemolysis. In almost all hemolytic anemias there is also subnormal function of the liver, so that stercobilinogen is not adequately removed from the blood by the liver and is excreted in the urine. Slight degrees of hepatic damage allow the escape of urobilinogen into the general circulation, to be excreted by the kidneys. Thus an excessive amount of urobilin

\* Urobilinogen excretion as measured by the Ehrlich reagent measures both urobilinogen and stercobilinogen indiscriminately.

FIG. 204. Schematic drawing explaining the changes of the metabolism of bile pigments in the various forms of jaundice. (Modified from Steigmann, Popper and Meyer: J.A.M.A., Vol. 122.)

BA – Unmodified bilirubin (indirect)  
 BB – Conjugated bilirubin (direct)  
 UROB – Urobilinogen (stercobilinogen)

is found in the urine of patients who have incomplete obstruction of the bile ducts. In portal cirrhosis, urobilin is found in excessive amounts in the urine, because it can pass from the portal to the systemic circulation through collateral venous channels without passing through the liver.

In infectious hepatitis there is increased urinary urobilin only at the beginning and end of the disease, since, it is believed, during the height of the disease the finer bile passages are completely obstructed.

Fecal excretion of urobilin is diminished when the liver is unable to excrete bilirubin properly because of obstruction or cellular damage. Increased fecal urobilin is indicative of increased production of bile pigment from excessive blood destruction.

**Bile Salts Determinations.** The concentration of bile salts in the blood and urine is increased in obstructive jaundice, but decreased in material obtained by duodenal intubation.

**Phosphatase Level.** The phosphatase level of the blood is increased in obstructive jaundice, since phosphatase spills back into the blood along with the other constituents normally excreted in the bile.

**Measurement of Excretion of Foreign Substances by the Bile. Bromsulphalein test.** This test is a sensitive indicator of mild hepatic dysfunction. It is performed after a carbohydrate breakfast, since fat in the plasma interferes with estimation of the color. After intravenous injection of 5 mg. of this dye per kilogram of body weight a blood sample (5 to 10 ml.) is withdrawn after forty-five minutes, which may contain 0 to 4 per cent of the dye injected. Retention of more than 6 per cent of the dye is abnormal.

Similar tests using other dyes ( $I^{131}$ , bengal rose,

azorubin S) are available. These tests are most useful in detecting liver damage in patients who do not have biliary obstruction, i.e., without hyperbilirubinemia.

#### TESTS BASED ON THE "DETOXIFYING" ACTION

Several tests assess the capacity of the liver to oxidize or conjugate various substances. The best known of these tests is the hippuric acid synthesis test.

**Hippuric Acid Synthesis Test.** This test measures the rate at which the liver can synthesize glycine, which, when conjugated with benzoic acid, forms hippuric acid. Actually, this test would seem to evaluate one phase of hepatic protein metabolism, rather than of a detoxifying mechanism. After an oral or intravenous dose of sodium benzoate the urinary excretion of hippuric acid is determined. In children five to eleven years of age 0.9 gm. of sodium hippurate is excreted in the first hour after oral administration of 2 gm. of sodium benzoate dissolved in 20 cc. of water.

The oral test is unreliable. The intravenous test is performed after a light carbohydrate breakfast—20 cc. of 8.85 per cent sodium benzoate are injected over a five- to ten-minute period. In the hour following injection adults excrete from 0.7 to 1.1 gm. of hippuric acid. The test is of no value when the blood urea nitrogen is elevated.

#### BIOPSY OF THE LIVER

Histologic examination of liver tissue obtained by needle biopsy or surgical exploration may furnish valuable diagnostic and prognostic data in many instances.

## HEPATIC DISORDERS

### CIRCULATORY DISTURBANCES

#### CHRONIC CONGESTION OF THE LIVER

**Etiology.** Cardiac failure (p. 893) is the principal cause of passive congestion of the liver. Though acute myocardial decompensation such as that associated with the crises of hemolytic anemias and with hypertensive acute glomerulonephritis will produce temporary passive hyperemia of the liver, more striking changes result from the prolonged passive congestion associated with chronic disease of the heart. Long-standing pulmonary disease with stasis in the right side of the heart will also engorge the liver. Occasionally a collection of pleural fluid or a thoracic tumor, by compressing the inferior vena cava, may retard the return of blood from the liver.

As the liver becomes congested, the central veins are distended, but the liver cords remain intact. With continuation of the

hyperemia the liver cells surrounding the central vein undergo degenerative changes due to anoxemia and become atrophic, giving the liver the appearance described as the nutmeg liver.

The large firm liver of either of these two stages may result in some pain or tenderness in the hepatic region. Subclinical or mild jaundice may be present.

With long-standing and particularly with recurrent episodes of congestive cardiac failure, hepatic fibrosis (cirrhosis) may occur, which involves either or both of the portal and central portions of the lobule. It is thought that infection in combination with venous stagnation is productive of cirrhosis.

#### JAUNDICE

**Clinical Forms.** Jaundice is the yellow coloration of the body tissues and fluids caused by excess bilirubin. It is usually

apparent when the serum bilirubin reaches levels of 2.5 to 3 mg. per 100 ml. (range, 1 to 7 mg.). Conjugated bilirubin causes more intense jaundice than unmodified at equal blood concentrations, because it is more diffusible, being water soluble. The bile pigments apparently bind easily to elastin, a fact which accounts for the unequal staining of various tissues and for the persistence of cutaneous pigmentation after the blood bilirubin level has fallen during recovery.

The most useful classification divides jaundice into hemolytic (indirect-reacting bilirubin) and obstructive (direct-reacting bilirubin) varieties. The obstructive type is further divided into extrahepatic and hepatocellular or intrahepatic obstruction.

**Hemolytic jaundice.** This type of jaundice results from excessive destruction of hemoglobin with the creation of more bilirubin in the plasma than the liver can excrete, despite its ability to increase its excretion of bilirubin manyfold. The bilirubin is the indirect-reacting form, which is not excreted into the urine. Since both forms of bilirubin are bound to serum albumin, it is difficult to understand why conjugated bilirubin appears in the urine, and the unmodified variety does not. There is an increase of fecal urinary urobilin, since the liver is excreting more bilirubin than usual. Hemolytic jaundice may occur in the congenital hemolytic syndromes (thalassemia, sickle cell anemia, congenital microspherocytosis) and in acquired hemolytic anemias of various causes.

The normal liver, as indicated, is capable of increasing the excretion of bilirubin tremendously. During periods of anoxia or infection, however, it may be so handicapped as to be unable to handle even the usual excretion of bilirubin. The liver of the newborn is normally deficient in one or more enzymes and cannot excrete bilirubin as well as the adult liver. Genetic defects of these enzymes for bilirubin conjugation occur in congenital familial nonhemolytic jaundice with kernicterus (Crigler-Najjar disease) and in constitutional hepatic dysfunction (Gilbert's disease) with resultant elevations of indirect-reacting bilirubin.

**Obstructive jaundice.** Under usual circumstances bilirubin is conjugated with glucuronide to form the direct-reacting variety and is excreted into the intestine. When this exit is blocked, the conjugated

bilirubin enters the blood stream, and jaundice ensues. This type of jaundice is termed regurgitative or obstructive. It may be the result of rupture of the biliary canaliculi due to congenital or acquired obstruction of the bile ducts (extrahepatic) or to obstruction of the canaliculi by swollen hepatic cells as in hepatitis (hepatocellular) or to fibrotic changes in cirrhosis. It is believed that the bile passes into the lymphatics and through the thoracic duct into the blood.

Direct bilirubin is secreted by the renal tubules and appears in the urine; since less bilirubin reaches the intestine than normally, the fecal and urinary concentrations of urobilin are decreased, or urobilin is absent with complete obstruction. The concentration of bile salts is also elevated in the plasma with obstructive jaundice, and they appear in the urine.

In many conditions there is a combination of hepatocellular dysfunction and obstruction of the bile ducts so that plasma concentrations of both direct- and indirect-reacting bilirubins are elevated.

**Clinical Manifestations.** Jaundice, seen first in the sclera and conjunctiva, soon becomes visible in the mucous membranes of the lips, hard palate and sublingual area, and finally stains the skin. Edematous areas and paralyzed parts may show little or no discoloration. Jaundice may be missed in artificial light; it varies in color and intensity from pale yellow through deeper shades of orange to many hues of green. Bilirubin imparts an orange color to the skin; its oxidation product biliverdin is responsible for the green color. The different icteric tints are dependent upon the proportions and amounts of these two pigments. The sweat, breast milk and blister fluid become bile-stained. Tears, saliva and gastric and pancreatic juices are not stained. The cerebrospinal fluid is only slightly discolored, but may become stained deeply if there is meningeal irritation. As a rule there are no manifestations other than the skin discoloration referable to hemolytic jaundice. In obstructive jaundice the urine is discolored, and the stools are clay-colored with an increased fat content. Pruritus and bradycardia in severe obstructive jaundice are ascribed to the increased concentration of bile salts in the body fluids. Although high levels of unconjugated bilirubin are held responsible for kernicterus of newborn infants with hemolytic disease, circulating bilirubin or

Table 89. Laboratory Findings in Different Types of Jaundice

Laboratory Studies		Hemolytic (or Prehepatic) Jaundice	Obstructive Jaundice			
Test	Extrahepatic		Intrahepatic or Hepatocellular			
	Incomplete		Complete	Acute	Chronic	
Urine	Bilirubin	Absent	Present	Present	Present	Present
	Urobilinogen	Increased	Normal	Decreased	Normal, increased or decreased	Normal
Stool	Urobilinogen	Increased	Normal	Acholic	Normal, increased or decreased	Normal
Blood	Conjugated bilirubin	Normal	Increased	Increased	Increased	Increased
	Total bilirubin	Increased	Increased	Increased	Increased	Increased
	Serum transaminase*	Normal (5–40 units)	57–320 units		540–1890 units	13–286 units
	Alkaline phosphatase	Normal	Increased	Increased	Normal or increased	Normal or increased
	Ratio $\frac{\text{cholesterol esters}}{\text{total cholesterol}}$	Normal	Decreased	Decreased	Decreased	Decreased
	Cephalin flocculation	Normal	Normal	Normal	Increased	Increased
	Thymol turbidity	Normal	Normal	Normal	Increased	Increased
	Thymol flocculation	Normal	Normal	Normal	Increased	Increased
	Prothrombin time	Normal	Normal	Normal or increased	Normal or increased	Normal or increased
	Serum albumin	Normal	Normal	Normal	Normal	Decreased
Serum globulin	Normal	Normal	Normal	Normal	Increased	

\* Serum transaminase activity parallels active cellular destruction. Levels are *very high* in early stages of hepatitis and are diagnostic; they are moderately elevated in biliary cirrhosis, Laennec's cirrhosis and obstructive jaundice.

bile salts are not the cause of the cerebral dysfunctions of severe hepatic disease evident as noisy delirium, flapping tremors of the hands, coma and electroencephalographic changes. This syndrome of hepatic encephalopathy is more likely related to increased blood levels of ammonia. Bleeding from the oral mucous membranes or gastrointestinal tract secondary to prothrombin deficiency is a frequent accompaniment of jaundice.

#### CONSTITUTIONAL HEPATIC DYSFUNCTION

(GILBERT'S DISEASE, FAMILIAL NON-HEMOLYTIC ICTERUS; HEREDITARY NONHEMOLYTIC JAUNDICE, CONSTITUTIONAL HYPERBILIRUBINEMIA)

This benign hereditary condition was delineated by Gilbert in 1901 and named

*cholémie simple familiale*. Its sole clinical manifestation is icterus, which may become apparent at any age. The inborn metabolic error responsible for the inability to conjugate bilirubin with glucuronic acid is a deficiency of the hepatic enzyme, glucuronyl transferase (p. 281). The defect is transmitted by an autosomal dominant gene.

Other than easy fatigability in some patients and occasional anxiety which may be engendered by fluctuations in intensity of jaundice, there are no symptoms. The elevated bilirubin is always indirect reacting, rarely exceeds 6 mg. per 100 ml. and may be intermittent or persistent. The diagnosis of constitutional hepatic dysfunction is made by exclusion of hemolytic processes. A mild hemolytic disorder without anemia may be

differentiated by estimation of fecal urobilinogen excretion. The bilirubin clearance test may be helpful; patients with Gilbert's disease show impaired ability to clear the blood of injected bilirubin. Liver biopsy specimens, unless examined for enzymatic activity, show no changes.

The disorder does not impair health or life expectancy.

#### CONGENITAL FAMILIAL NONHEMOLYTIC JAUNDICE WITH KERNICTERUS

(CRIGLER-NAJJAR DISEASE, CONGENITAL HYPERBILIRUBINEMIA)

This rare type of congenital severe hyperbilirubinemia, first described by Crigler and Najjar (1952) in eight members of a single large kinship, is a serious disorder in which abnormally high plasma bilirubin levels and encephalopathy result from hepatic disability to conjugate bilirubin with glucuronide. Deficiency of the hepatic enzyme, glucuronyl transferase, transmitted as an autosomal recessive trait, is the basic hereditary molecular defect. Severe central nervous system disturbances of the extrapyramidal type usually appear during the early weeks of life, but may develop later in infancy or during early childhood. Febrile episodes, apparently of central nervous system origin, are common.

Bile thrombi are present in the hepatic canaliculi, but the parenchymal cells appear normal. Evidences of excessive hemolysis are absent. There is bile staining of the basal nuclei, characteristic of kernicterus.

Serum bilirubin levels range from 10 to 44 mg. per 100 ml., with 80 to 90 per cent of the total in the indirect form. Urobilinogen excretion in the urine is increased, with less than half the normal amount present in the feces. The bilirubin excretion test is abnormal. Absence of evidences of hemolytic disease, of blood group incompatibilities and of obstructive jaundice helps to distinguish this disorder from the common causes of neonatal jaundice.

The *prognosis* is poor; the extent of central nervous system involvement determines the duration of life. Most patients die during early infancy, but a number of young children with the disorder are recorded, and Jervis has reported an affected woman forty years of age with the dystonia syndrome typical of kernicterus. By inhibiting oxygen consumption and by uncoupling oxidative

phosphorylation, bilirubin is toxic to cerebral tissue, especially in its unmodified form, which is lipophylic. Conjugated bilirubin, which is water soluble, does not stain cerebral tissue. Thus the encephalopathy of this disorder may be attributed to the hyperbilirubinemia. A mutant strain of Wistar rats described by Gunn has congenital hyperbilirubinemia and kernicterus. Administration of sulfonamides intensifies the cerebral damage and staining in these animals. A similar potentiating effect of sulfonamide drugs on the toxicity of bilirubin has been observed in premature infants with jaundice.

*Treatment* is symptomatic and supportive; sulfonamide drugs should be avoided.

#### CHRONIC IDIOPATHIC JAUNDICE

(DUBIN-JOHNSON SYNDROME, MAVERO-HEPATIC ICTERUS, BLACK LIVER JAUNDICE)

This disorder, in which jaundice is the single invariable symptom, is characterized by a green-black discoloration of the liver due to accumulation of coarsely granular brown pigment in the parenchymal cells. Often familial, it is benign and lifelong and is probably the result of an inherited disability of the hepatic cells to excrete conjugated bilirubin. In two thirds of the cases jaundice is apparent before the age of twenty; the time at which it is first noted varies from early infancy to adult life. About one quarter of the cases are asymptomatic. Pain over the liver is the most common symptom, and weakness, anorexia, nausea, vomiting and diarrhea are less frequently complaints, recurring with each bout of jaundice.

The liver is enlarged and tender in about half of the cases. Bile and increased urobilinogen are often present in the urine; the stools may be acholic, and hepatic function tests are sometimes abnormal during episodes of jaundice. The gallbladder is seldom visualized by oral cholecystography. Jaundice may be intermittent or persistent with fluctuations in intensity.

The maximum values of the fluctuating concentrations of serum bilirubin range from 2.4 to 19 mg. per 100 ml.; it is predominantly of the conjugated type. Biopsy specimens of the liver are diagnostic; the cells have centrilobular distribution of the pigment granules, which are probably a lipofuscin. The *prognosis* for life is good.

## INFECTIONS

### INFECTIOUS HEPATITIS

(VIRAL HEPATITIS, ACUTE CATARRHAL JAUNDICE)

**Etiology.** There are at least two forms of infectious hepatitis which are etiologically distinct, but pathologically and clinically indistinguishable (see table on p. 706). Each is caused by a virus or strains of viruses to which immunity is established after infection, but there is no cross immunity. The naturally transmitted infection is termed *infectious hepatitis*, or *endemic* or *epidemic hepatitis*; the one artificially transmitted by administration of plasma or blood or of vaccines made from human serum is termed *serum hepatitis*, or *homologous serum hepatitis*.

**Infectious hepatitis (viral hepatitis A; IH hepatitis).** The gastrointestinal tract is the usual portal of entry for the virus, which has also been demonstrated in the blood and feces during the preicteric and early icteric stages of the disease. It may also be present in the stools until recovery is complete.

**Serum hepatitis (viral hepatitis B; SH hepatitis).** Injection of human serum products (convalescent serums, whole blood, plasma, the older type of yellow fever vaccine or the topical application of human thrombin as a hemostatic agent in neurosurgery) may result in an infection clinically and pathologically indistinguishable from the more common infectious hepatitis, which has a natural epidemiology. The virus (or viruses) transferred by the injections of infected serum, however, is a different strain (or strains) than the one of the naturally transmitted infection. Even minute amounts of infective material as in incompletely cleansed syringes may be causative. Presumably the virus can survive in stored serum or plasma for a long time and can withstand desiccation and various other physical and chemical treatments.

**Incidence.** There is a high incidence (up to 90 per cent) of nonicteric cases during epidemics of infectious hepatitis. The seeming rarity of the illness below the age of two years has been attributed to lack of exposure. It is now apparent that infectious hepatitis is often anicteric in infants and young children and is therefore undetected rather than nonexistent. Above the age of four years the attack rate, i.e., patients with jaundice, during an epidemic bears no relation to age. The infected nonicteric infant may serve as a reservoir from which sporadic

cases and small epidemics of jaundice in older children and adults are initiated. Non-icteric "carriers" of the virus of infectious hepatitis are known to exist; the extent to which they disseminate infection is undefined.

There is no natural epidemic pattern for serum hepatitis, although the infection may occur in epidemic form when the agent is transmitted through vaccines, plasma or blood to large population groups as during World War II. *Transplacental passage* of the virus of serum hepatitis apparently infects the fetus and is responsible for hepatitis in newborn and young infants. This does not appear to be so with the virus of infectious hepatitis.

**Pathology.** Serial biopsy studies in adults show the same pathologic changes in the liver in both types of hepatitis. The hepatic lobules show varying degrees of cellular necrosis and autolysis, beginning in the center of the lobules and spreading radially as the disease advances. There is thickening of the reticular fibers. Evidences of cell regeneration, i.e., increased mitotic figures, are prominent in the early stages of the disease. Accompanying the hepatocellular necrosis is widespread infiltration with inflammatory cells, polymorphonuclear leukocytes, lymphocytes, macrophages and plasma cells. In the later stages lymphocytes predominate. There is a diffuse reticuloendothelial reaction; the reticulum becomes thickened and assumes the staining properties of collagen. The periportal areas are widened because of infiltration with large numbers of macrophages, plasma cells and lymphocytes and smaller numbers of polymorphonuclear cells and eosinophils. Proliferating bile ducts appear in the perilobular portal areas, and bile stasis is visible. The clinical manifestations of viral hepatitis are expressions of the hepatocellular necrosis, intrahepatic biliary obstruction, portal obstruction and diffuse inflammatory reaction in the liver. With recovery, complete regeneration of the liver cells occurs without scarring. In fulminating and fatal cases the hepatic changes are typical of yellow atrophy. About 15 per cent of the fatal cases studied by Lucké showed changes in the brain consisting in acute degeneration of ganglion cells and mild meningoencephalitis.

**Clinical Manifestations.** The incubation period of infectious hepatitis preceding the onset of jaundice is fourteen to forty days; if measured to the onset of initial symptoms, it may be three to five days less.

The incubation period of serum hepatitis is 60 to 135 days.

In most patients symptoms begin three to five days before the appearance of jaundice. Fever, malaise, mild headache and chilliness are present at the onset. Signs of a mild upper respiratory tract infection are found in many patients. Anorexia is an invariable early symptom, frequently followed by nausea and vomiting. The breath is often foul, and older children may complain of a sour or bitter taste. Upper abdominal distress and pain are frequent complaints. Constipation is more common than diarrhea. The presence of bile in the urine is the first sign of developing jaundice and usually precedes its clinical appearance by one to three days.

In about one sixth of all patients the disease is manifest by the appearance of jaundice without any preceding symptoms. Jaundice may vary from a slight discoloration of the scleras, where it is first seen, to a deep pigmentation involving the entire body. Fever usually disappears with the onset of icterus, but anorexia continues, and severe prostration and vomiting secondary to pylorospasm may occur, especially in deeply jaundiced patients. The stools are light or clay-colored at this stage. Pruritus is infrequent in the jaundiced child. In severely ill children extreme lassitude and irritability may be present.

In more than half the cases the liver is enlarged and tender; in a small number there is an enlarged tender spleen. Ascites is almost never present. Bradycardia, common in the adult, is usually absent in children. Seborrheic dermatitis, morbilliform rashes and hemorrhagic phenomena are uncommon.

**Diagnosis.** The van den Bergh reaction is

direct during the early days of jaundice and changes to a biphasic reaction as recovery begins. During the terminal phase of recovery the reaction may be indirect only. The serum bilirubin is increased, ranging as high as 10 mg. per 100 ml. With the onset of jaundice there is an increased urinary excretion of urobilinogen, due to the inability of the damaged liver to excrete reabsorbed urobilinogen, formed from bile which is still entering the intestine. As the jaundice becomes more intense, owing to complete regurgitation of bile so that it does not enter the intestine, urobilinogen disappears from the urine, since it is not being formed in the intestine. With the subsidence of jaundice resulting from the resumption of excretion of bile into the intestine, urobilinogen is again formed and appears once more in the urine in large quantities, the liver still being incapable of removing it from the blood (Fig. 205).

The bromsulphalein retention test tends to parallel the retention of bilirubin in the blood, but is often abnormal for a longer time. The serum glutamic-oxaloacetic and glutamic-pyruvic transaminases are elevated early in the course; their return to normal heralds the end of the active disease and the beginning of recovery.

There is often a large reduction in the ester fraction of the plasma cholesterol and a lesser one in total cholesterol during the acute phase of the disease. Early in the recovery period levels of both total and esterified cholesterol may be temporarily higher than normal. Plasma phosphatase concentration is increased during the early icteric phase, but not always to abnormal levels. The cephalin flocculation and thymol turbidity tests are

FIG. 205. Schematic curve of the results of qualitative analysis for bilirubin and urobilinogen in a typical case of parenchymatous jaundice with intrahepatic obstruction. (From Steigmann, Popper and Meyer: J.A.M.A., Vol. 122.)

fairly reliable indicators of activity of the hepatitis, as are the transaminase levels. The sedimentation rate is increased in some cases. There are no significant changes in the serum protein concentration on routine determination, but an increase in gamma globulin can be demonstrated by electrophoretic analysis.

No single test furnishes complete information about the functional state of the liver, so that, to ascertain the degree of functional restoration, a group of tests must be used. There are no consistent changes in the total leukocyte count, but a monocytosis as high as 25 per cent is occasionally observed. Hypoglycemia and acetonuria are frequent findings. On occasion serologic tests for syphilis are falsely positive.

The diagnosis may often be made several days before the appearance of jaundice by means of the methylene blue test (Myers) or the Harrison spot test (Godfried). Both tests are based on the presence of small amounts of bilirubin in the urine.

In the *methylene blue test* 2 drops of Löffler's methylene blue solution are added to 10 cc. of urine. The solution remains dark blue if no bilirubin is present, but turns a brilliant green when bilirubin is present.

In the *Harrison spot test* 10 cc. of urine are mixed with 5 cc. of 10 per cent barium chloride solution and filtered. The filter paper is then spread on another dry piece of filter paper, and 1 or 2 drops of Fouchet's reagent are dropped on the precipitate. A green or blue color indicates bilirubin.

**Differential Diagnosis.** The differential diagnosis of infectious hepatitis presents few difficulties. The finding of bile in the urine, the acholic stools and the direct van den Bergh reaction establish the obstructive nature of the jaundice and rule out the acute hemolytic anemias. Though the other causes of obstructive jaundice should be considered possibilities, *leptospirosis* is the condition most often confused with infectious jaundice. The labial herpes, hemorrhagic exanthem, fever, leukocytosis, muscle pains and albuminuria occurring in leptospirosis should serve to distinguish the two diseases. The specific agglutination test, the isolation of the spirochete from the blood or serum, or the successful inoculation of a guinea pig confirms the diagnosis of leptospirosis. Involvement of the liver in infectious mononucleosis may mimic viral hepatitis at times.

Stokes summarizes the differences between infectious hepatitis and serum hepatitis as follows:

	Infectious (Epidemic) Hepatitis (A)	Serum Hepatitis (B)
Symptomatology	More stormy onset with a chill or chilliness and a sudden rise in temperature	Slow insidious onset with mild prodromes and little fever except in the fatal cases
Route of inoculation	Oral, rectal or parenteral	Parenteral only
Incubation period	14-40 days	60-135 days
Usual age range	Below 30 years	All ages
Epidemic spread	Common	Rare, if at all
Virus demonstrated	Blood and feces	Blood, ascitic fluid and arthritic fluid
Blood carriers	0	+
Immunity	Homologous immunity present; cross immunity absent	Homologous immunity present (up to 1 year); cross immunity absent
Increased susceptibility	Previous attack of serum hepatitis increases susceptibility	Previous attack of epidemic hepatitis increases susceptibility
Gamma globulin for prophylaxis	Prevents clinical disease; does not prevent infection	Not effective

**Course and Prognosis.** Infectious hepatitis has its highest incidence, but lowest mortality, among children of school age. Compared with the clinical course in adults, the disease is milder and of shorter duration in this group, the average case with jaundice lasting three weeks, with a range of four to eighty days. Not infrequently a child feels well by the time the jaundice appears; usually the other clinical manifestations are gone by the seventh day of jaundice. Apparently much more common among children than the icteric form of the disease is a milder, but immunizing, anicteric infection caused by type A hepatitis virus with symptoms predominantly those of an intestinal or respiratory illness.

"Congenital" or neonatal viral hepatitis occurs in the early weeks of life, apparently acquired in utero by transplacental transmission of virus B. Characterized by early onset of jaundice, hepatosplenomegaly, bilirubinuria and acholic stools, its definitive diagnosis by liver function tests is often difficult; twelve infants in one series of forty

subjected to surgery were found to have hepatitis. Identification of most reported cases has been by needle or surgical biopsy or at necropsy. Cirrhosis is a sequel in about one fourth of affected infants. Complete recovery without relapse is usual, but in a small number of instances viral hepatitis occurs in a fulminant form. This disastrous form of the disease often leads to death in less than ten days. Infrequently the course is slowly progressive with death within two to nine months in hepatic failure or with clinical and laboratory remission after several months. In the latter case the final outcome is in doubt; the suggestion has been made that chronic fibrosis of the liver (Laennec's cirrhosis) may develop when factors are encountered which, acting synergistically with the virus, lead to fibrosis, e.g., nutritional deficiency, metal and chemical poisoning, alcoholism, infections with amebae, *Salmonella typhosa*, *S. choleraesuis*, and the like.

**Treatment.** This is symptomatic. Rest in bed until jaundice disappears is advisable, since activity aggravates the symptoms, and it is impossible to determine which patient will have yellow atrophy. Application of local heat may relieve epigastric distress, but at times sedation is required. For this purpose chloral hydrate is preferable to the barbiturates or opiates, which are hepatotoxic. Anorexia and vomiting may also be ameliorated by sedation, but severe vomiting is often dramatically stopped by intravenous administration of 5 per cent glucose in isotonic solution of sodium chloride. Frequent small meals of carbohydrate and protein (fruit juices, carbonated drinks, skimmed milk, gruels, lean meat) are better tolerated than large meals at longer intervals. Fats are moderately restricted, since they tend to aggravate nausea and vomiting, especially when bile is completely absent from the intestinal tract. A full, unrestricted diet may be given as soon as the patient can tolerate it.

On theoretic grounds the inclusion of supplements of the entire vitamin B complex to the diet should aid in the prevention of further hepatic injury. In fulminating and comatose cases exclusion of protein from the diet and bowel sterilization with a broad-spectrum antibiotic, preferably neomycin, suppress the production of toxic nitrogenous compounds in the intestines by bacterial degradation of protein. Cleansing enemas and magnesium sulfate purgation are at times of value for the same purpose. These measures

help prevent or minimize the accumulation of ammonia in the blood and the neurologic manifestations of hepatocerebral intoxication. Daily intravenous administration of albumin may be of value if edema or ascites occurs. Corticosteroids appear to be of benefit on occasion in fulminating as well as in chronic hepatitis.

The therapeutic value of L-arginine and L-glutamic acid in hepatic coma is as yet undetermined. Glutamic acid detoxifies the circulating ammonium ion by forming innocuous glutamine; arginine, by providing intermediates for the Krebs' ornithine cycle in the hepatic cells, removes ammonia as urea. However, the role of ammonia in the genesis of hepatic encephalopathy is not satisfactorily defined. Methionine and choline are of no value in treatment and may be toxic to patients with hepatic coma. Similarly, sulfonamides, ammonium salts, urea, acetazolamide and chlorothiazide should be avoided. In the rare case with hemorrhagic phenomena, vitamin K should be given parenterally.

Children usually do not require as prolonged convalescence as do adults, and most may quickly resume normal activities.

Intramuscular injection of human gamma globulin in doses as small as 0.02 ml. per kilogram of body weight is effective prophylaxis against type A virus infection, even when given as late as six days before the expected onset of symptoms. It appears that gamma globulin does not prevent infection in exposed susceptibles, but attenuates the disease to a subclinical level, and in many instances results in acquisition of active immunity. Gamma globulin has no protective action against infection with type B virus (homologous serum hepatitis).

The "enteric precautions" utilized for any stool-borne infection should be observed by family contacts and personnel caring for patients with viral hepatitis. Since the duration of infectivity of stools is undetermined, quarantine and isolation regulations are based on arbitrary grounds.

For Parasitic Infestations and Echinococcus Disease, see page 574.

#### LIVER ABSCESS

##### SOLITARY ABSCESS

The pyogenic solitary abscess is an occasional complication of a variety of infections, including typhoid fever, bacillary dysentery, Brucella infection, influenza, tuberculosis and

Friedländer's bacillus infection. Rarely it is secondary to ileocecal actinomycosis as a large honeycomb abscess. Most often, however, the single hepatic abscess is due to the *Staphylococcus* or *Streptococcus*. The infective agent may reach the liver directly by a penetrating injury or by extension from an adjacent infected area, as, for example, from a pleural empyema. Occasionally roundworms have resulted in liver abscess by wandering into the bile ducts, causing hepatic injury and permitting secondary pyogenic infection. Amebic abscess, the commonest solitary abscess of adults, is almost unknown in children in the United States.

**Clinical Manifestations.** Occasionally an abscess of the liver may be latent if it is well encapsulated, or it may be overshadowed by the symptoms of the disease from which it has its origin. More often symptoms are present, of which fever is the most constant, usually being accompanied by chills, sweating and prostration. Nausea, vomiting, diarrhea and meteorism may be prominent symptoms. Pain is usually present over the liver and may be severe; at times it may be referred to the right shoulder or the epigastrium. Upward enlargement of the abscess may produce cough or dyspnea by irritation of the diaphragm. Cachexia is a feature of the longstanding abscess. Mild icterus is present in many and ascites in a few cases. Moderate enlargement of the liver, usually of the right lobe, both upward and downward occurs.

**Diagnosis.** The upward enlargement of the liver can be demonstrated on the roentgenogram. Tenderness may be elicited by palpation or by mild percussion with the fist over the liver. Repeated exploratory punctures until the abscess is located will furnish a positive diagnosis, but it is generally agreed that this procedure should not be used unless incision and drainage are carried out immediately after obtaining pus. Such exploratory punctures are safest when the liver is exposed by laparotomy; this procedure is always advisable in infants.

**Complications.** The abscess may rupture spontaneously into the thorax, the peritoneum, the intestines or, rarely, the pericardium. Metastatic abscesses of the lung or brain may occur. Subphrenic abscess is an occasional complication.

**Treatment.** Appropriate antibiotics should be given for pyogenic abscesses, and emetine for amebic abscesses. Surgical drainage should be performed when necessary.

## MULTIPLE ABSCESSSES

Multiple liver abscesses arise from septicemia or from ascending infection of the portal vein (pyelophlebitis). In the newborn infant infection extending along the umbilical vein is a common cause of multiple hepatic abscesses. These abscesses are small and usually are not detected during life.

## CIRRHOSIS

**Etiology.** Cirrhosis is characterized by degeneration of hepatic cells, followed by a nodular disorganization of regenerated cells with distortion of the vascular pattern and an increase in fibrous connective tissue. Cirrhosis may follow a number of hepatic disorders, although frequently the etiology is unknown. Severe or prolonged hepatic cellular damage is common to all known conditions predisposing to cirrhosis. However, even though the initial disturbance becomes quiescent, the cirrhotic process may continue. The progression may be related in part to cellular anoxia produced by constrictive fibrous bands, which results in further cellular damage and further attempts at regeneration with additional fibrosis. Complete understanding of the pathogenesis of cirrhosis remains to be achieved. Fibrosis without disturbance of the hepatic architecture should not be termed cirrhosis.

Cirrhosis may have its origin in a congenital defect as in hepatolenticular degeneration (Wilson's disease). This is a familial disorder of copper metabolism (p. 257), in which copper is deposited in the liver. The cirrhosis may cause death before symptoms of central nervous system involvement are evident.

Biliary cirrhosis may follow prolonged biliary obstruction from any cause, atresia of the bile ducts being the most common cause during infancy. Cirrhosis secondary to prolonged vascular congestion may occur with cardiac decompensation and with intrahepatic obstruction of the portal vein. Chiari's disease (thrombosis of the hepatic vein) may also be responsible for cirrhosis.

Numerous infections of the liver may ultimately lead to cirrhosis. Infectious hepatitis would appear to be the most common one during childhood. Bacterial infection of the umbilical vein in newborn infants or of the pelvic or mesenteric veins in older children may extend to the liver and cause cirrhosis. Syphilis, malaria and kala-azar are also relatively common causes. Cirrhosis is seen in

patients who recover from acute hepatic poisoning, as for example with carbon tetrachloride.

It is probable that some factor or combination of factors, in addition to cellular damage itself, is required to produce cirrhosis. Such factors may include general or specific genetic defects, prolonged exposure to toxic agents and iso-immunization. See cirrhosis in Indian children (p. 711).

**Incidence.** Cirrhosis is not common among children in the United States. In the Near East and in the Orient biliary cirrhosis is relatively frequent (p. 711).

**Forms of Cirrhosis.** Traditionally, cirrhosis has been divided into portal (Laennec's cirrhosis) and biliary types. In children mixed forms of the two pathologic types of cirrhosis are more common than either of the pure forms.

In *portal cirrhosis* bands of fibrous tissue radiate from the portal triad and surround the hepatic lobules; there is degeneration of hepatic cells with evidence of a chronic inflammatory reaction. *Biliary cirrhosis* secondary to obstruction of the bile ducts is characterized by accumulation of bile in the distended canaliculi and fibrosis radiating from the distended bile ducts. As both types progress, however, this differentiation is lost; frequently it is impossible to classify the type of cirrhosis when confronted with the nodular fibrotic changes characteristic of the later stages of the disease.

**Clinical Manifestations.** The liver is usually enlarged and firm; the edge may be smooth or nodular. In late stages the liver may contract, but even at autopsy it is usually enlarged.

Other manifestations of cirrhosis occur only (1) when the liver fails in some of its physiologic functions, or (2) when the pressure of the portal vein is sufficiently elevated to produce symptoms.

The functional reserve of the liver is great; indeed, cirrhosis may exist for many years, or death may occur by exsanguination from esophageal varices without evidence of deficiency of hepatic function. When cirrhosis is sufficiently advanced to interfere with hepatic function, many nonspecific symptoms such as malaise, anorexia, bloating and loose, frequent stools may appear.

Low grade fever is a common symptom. Serum albumin is depressed, and peripheral edema may be present. The serum globulin is usually elevated, but may be normal. Jaundice is common; usually both the direct- and

indirect-reacting serum bilirubin levels are elevated, but either may predominate. Pruritus and bradycardia may accompany the jaundice, but are not common in children. Hypoprothrombinemia with epistaxis or other bleeding manifestations is frequent; failure of prothrombin to rise after administration of vitamin K is a grave sign. Anemia is usually present. Neurologic signs, such as coma and convulsions, are frequent in the terminal phase or during crises of hepatic insufficiency. Spider angiomas and liver palms occur, but less commonly than in adults. Symptomatic hypoglycemia is rare. Growth retardation is common and may be extreme.

Symptoms resulting from obstruction of the portal venous flow include enlargement of the spleen, the formation of gastric and esophageal varices, ascites and collateral venous circulation in the veins of the abdominal wall (*caput medusae*). Ascites may be related to hypoproteinemia and/or portal hypertension and may be massive. The splenomegaly may be associated with hemolytic anemia, neutropenia or thrombocytopenia (Banti's syndrome, p. 986). Hemorrhage from esophageal or gastric varices may be the initial sign of cirrhosis; such hemorrhages may be made more severe by hypoprothrombinemia or thrombocytopenia. Hemorrhoids and varicoceles of the spermatic veins are uncommon in children. Clubbing of the fingers and toes may occur in the more protracted and severe cases.

In the so-called *Cruveilhier-Baumgarten cirrhosis*, which develops as a result of failure of obliteration of the umbilical vein, a well marked *caput medusae* is seen. In addition to the striking periumbilical venous dilatation, a loud venous murmur is audible at the umbilicus. There is no ascites associated with this cirrhosis.

**Diagnosis.** With the exception of biopsy of the liver, no specific diagnostic measures are available. Abnormal hepatic function may be demonstrated by hypoalbuminemia with reversal of the albumin-globulin ratio due in part to hyperglobulinemia, by hypoprothrombinemia and by low levels of cholesterol esters in the blood. The concentration of blood ammonia may be high and be responsible for coma and convulsions. If jaundice is not present, poor excretory function may be demonstrated by retention of bromsulphalein. If jaundice is present, bile may appear in the urine, and the urinary urobilin may be increased. The cephalin flocculation, thymol turbidity and thymol flocculation tests may be

positive. These tests, which reflect the presence of abnormal proteins in the plasma, are often normal, however, even in the presence of severe hepatic dysfunction. Biopsy of the liver by needle aspiration is being used increasingly for diagnostic and prognostic purposes.

**Treatment.** The patient with biliary cirrhosis may be greatly improved if any existing obstruction is relieved. No specific treatment is available for other forms of cirrhosis.

In milder cases of cirrhosis a high caloric diet with liberal protein content and fat as desired by the patient should be provided. If signs of encephalopathy are noted, the protein should be discontinued or greatly reduced. Supplements of the B vitamins may be beneficial, as may added choline. Methionine is valueless and may actually precipitate coma. In anorexic patients glucose should be administered intravenously. Edema and/or ascites is treated by rigid restriction of sodium (200 mg. daily); diuretics may prove beneficial, particularly chlorothiazide (Diuril), but this should not be used if hepatic coma is present or impending. Corticosteroid therapy may have a favorable effect on ascites and deserves a trial in most cases. Massive ascites may require paracentesis; this procedure should be limited to patients with respiratory distress, owing to the dangers of peritoneal infection.

Measures which lower the concentration of blood ammonia may abolish or reduce the symptoms of hepatic encephalopathy. Such measures include a diet containing no or very little protein and the oral administration of broad-spectrum antibiotics to reduce the intestinal flora. The intravenous administration of arginine may have some added benefit by aiding in the removal of ammonia from the blood. Vitamin K should be administered if there is hypoprothrombinemia; if it is ineffective, as is often the case, transfusion of fresh blood may be required to supply prothrombin. Management of bleeding from esophageal or gastric varices includes sedation, avoidance of oral feeding, tamponade by means of the three-lumen Blakemore-Sengstaken tube, which may be lifesaving, and transfusions of whole blood. Several surgical procedures have been devised to reduce the pressure in the varices by shunting blood from the portal circulation to the systemic veins. The relative merits of these procedures and of other forms of surgical treatment are still to be assessed.

The over-all management of the child and his family, as in other chronic, progressive

disorders, requires a good deal of understanding on the part of the physician, who can do much to make the situation tolerable if he will take the time.

#### HEPATIC CIRRHOSIS WITH ARTHRITIS AND AMENORRHEA IN FEMALES

(KUNKEL'S SYNDROME; PLASMA CELL HEPATITIS)

Kunkel has drawn attention to a syndrome of chronic liver disease in young females, characterized by cirrhosis with intensive hepatic infiltration by plasmocytes, extreme hypergammaglobulinemia and clinical features such as arthritis, obscure febrile episodes and hormonal disturbances, not usually seen in Laennec's cirrhosis. A few cases may be sequels of anicteric viral hepatitis, but in most instances the etiology is unknown. The disease begins insidiously, usually about puberty, with fatigue or lassitude or occasionally with bleeding gums or epistaxis. Amenorrhea is an early symptom; at times acne, pigmented striae, hirsutism, moon facies and/or obesity are noted before signs of liver disease are present.

Hepatomegaly and splenomegaly are usually the earliest signs of liver disease. Spider telangiectases occur in most patients, and esophageal varices are present in about half the cases. Ascites develops only late in the course. Many have febrile episodes, at times associated with severe respiratory and cardiac disturbances. Swollen painful joints often accompanied by fever and hepatic pain are frequent. In two instances rheumatic nodules were found. The good nutritional status during the early stages of the illness is remarkable. Death from esophageal hemorrhage or hepatic coma usually occurs within ten years of onset.

In addition to the usual chemical changes of hepatic cirrhosis, the elevation of plasma gamma globulin is impressive; in one case it was 9.4 gm. per 100 ml. Jaundice is commonly present, and bromsulfalein retention is found in all cases.

At necropsy the liver is moderately enlarged and shows diffuse nodular cirrhosis, resembling the postnecrotic type. The inflammatory exudate in the liver contains a preponderance of plasma cells, and serial biopsy studies show a correlation of the number of these cells with the degree of hypergammaglobulinemia.

The response to corticosteroid therapy is often dramatic, resulting in complete remis-

sion in many instances. The ultimate effect of this treatment must await further observation.

### NUTRITIONAL LIVER DISEASES

Dietary protein deficiency produces two types of hepatic injury in experimental animals. One, acute massive hepatic necrosis with post-necrotic scarring, is caused by deficiency of sulfhydryl groups (cystine and methionine) and alpha tocopherol. Its analogue in human disease is the necrosis seen in fulminating viral hepatitis and various kinds of poisoning. The second type, fatty liver with fibrosis, results from the dietary deficit of lipotropic labile methyl groups (lecithin, choline and methionine). A number of clinical syndromes of human nutritional liver disease, collectively designated as the *kwashiorkor syndrome*, occur among native populations of tropical and subtropical regions. Owing to ready availability of carbohydrate-containing foods, the dietaries of these peoples are adequate in calories, but are deficient in protein; the various syndromes include the following:

1. *Classical kwashiorkor or malignant malnutrition* (p. 357).

2. *Protein malnutrition complicated by Senecio (ragwort) poisoning* in South Africa. The Senecio alkaloids are hepatotoxic and are apparently ingested as a contaminant of wheat bread. Hepatomegaly and ascites are characteristic.

3. *Protein malnutrition with siderotic cirrhosis of the liver* in native South African children. The iron pigment in the cirrhotic liver of these children appears to come from the iron cooking utensils in which their carbohydrate foods are prepared.

4. *Infantile and childhood cirrhosis* in Hindu children (see below).

5. *Vomiting sickness of Jamaica*, probably due to toxic substances in "bush teas" made from the bitter cassava or unripe ackee fruit, which produces severe hepatic damage in malnourished children. Severe vomiting after meals, associated with hypoglycemic manifestations, characterizes this disorder, which is epidemic in the winter months. Death occurs in many instances in two to three days.

6. *Veno-occlusive disease of West Indian children*, a third variety of nutritional liver disease in this region.

MILTON RAPOPORT

### INDIAN CHILDHOOD CIRRHOSIS

greater prevalence of cirrhosis of the liver in children in the tropics and subtropics than

in the temperate zones is generally recognized, but in two widely separated regions, Jamaica and India, it is sufficiently common to constitute a public health problem. There seem to be certain differences, however, between the types encountered in these two areas. The Jamaican cases, known also as veno-occlusive disease, have an abrupt onset with acute hepatomegaly and ascites followed by a sub-acute phase with persistent hepatomegaly, with or without ascites, and finally by chronic cirrhosis. By contrast, the onset of the cases in India is often insidious or subacute, and ascites is a later manifestation. (See also Etiology.) Whereas neonatal hepatitis, giant cell hepatitis and biliary cirrhosis secondary to congenital atresia of the bile ducts are seen in infants in India as in Europe and America, the frequent occurrence of cirrhosis of unknown etiology in many areas of India among children, generally between one and five years of age, justifies the separate clinical designation, "Indian childhood cirrhosis."

**Etiology.** The cause or causes responsible for this damage to the liver in Indian children are not known. Congenital syphilis, malaria and kala-azar do not seem to be factors. Poor nutrition has been blamed, but does not seem to be directly responsible, since the condition is infrequent among the poorest classes, among whom kwashiorkor is endemic.

The similarity of histologic changes in the liver to those in the chronic phase of viral hepatitis and the frequency of jaundice at some stage of Indian childhood cirrhosis have given rise to speculation whether some cases of the latter might represent viral hepatitis. Unlike the situation in Jamaica, where a toxic alkaloid in the bush tea consumed by children is believed to be responsible for the hepatic changes, no poison has been found in the diets of Indian children. It is possible that there may be different etiologic factors in the Indian cases. The common occurrence of several cases in the same family has suggested the possibility of a genetic factor or more likely of an environmental factor.

**Pathology.** Study of liver biopsy specimens obtained by the Vim Silverman needle has shown that the most constant change in the early stage is varying damage of the liver cells, either patchy or widespread. Fatty vacuolation of the liver cells is absent at all stages. Cellular infiltrates are often present. In the stage of cirrhosis there is postnecrotic scarring with regenerating nodules. Pseudolobulation is commonly present, though some cases show a basket-like network of fibrous tissue

with groups of liver cells with advanced degenerative changes. Occlusion of hepatic vein radicles, a common feature in the Jamaican cases, is apparently an uncommon feature in the Indian ones.

**Clinical Manifestations.** In the majority of instances the onset is insidious with vague symptoms of poor appetite and slight abdominal distention. The child lacks pep and is often peevish, and growth is retarded. Intermittent phosphaturia has been reported. Occasionally the onset is acute, comparable to that of viral hepatitis. Enlargement of the liver is invariably present from the beginning. The degree of hepatic enlargement varies; usually the liver extends to the umbilicus within a few months, contracting to some extent in the late stages, when it becomes increasingly firm. The surface of the liver may also feel granular, or rarely nodular. Jaundice is common in the late stages, and also often occurs for a short period in the early phase, or occasionally there is a history of preceding jaundice.

Fever is inconstant, but never high. At times there is a discoverable cause such as an upper respiratory tract infection, but more often there is none, and the fever seems to be due to further hepatic parenchymal destruction. The child deteriorates during such febrile episodes. Portal hypertension with ascites, evidences of collateral circulation and hematemesis may be terminal manifestations. Splenomegaly and hypoproteinemic edema are also common in the late stages. The clinical manifestations can be attributed to hepatic dysfunction (peevishness, poor appetite, pale stools), to portal hypertension (ascites, tympanites, hematemesis) and to hypersplenism in the late stages (anemia, leukopenia and purpura due to thrombocytopenia).

The course is prolonged from a few months to a year or two; even in the more severe and prolonged cases, recovery may occur and be complete as shown by liver biopsies. In general, however, the outlook is poor when the disease becomes far advanced.

**Diagnosis.** The diagnosis is obvious in the stage of cirrhosis with ascites, but in the earlier stage of vague symptoms the only definite sign is the enlarged firm liver. Other causes of hepatomegaly or hepatosplenomegaly, such as malaria, kala-azar, leukemia and various anemias must be excluded by appropriate laboratory tests. Liver biopsy has been helpful in questionable cases; the possibility of a bleeding tendency should first be

eliminated, and vitamin K should be administered before undertaking biopsy.

**Treatment.** Treatment is mainly symptomatic. Hematemesis may necessitate transfusion, and extensive ascites may require drainage.

## NEOPLASMS

See page 1352.

## CYSTS OF THE LIVER

Large, solitary nonparasitic cysts of congenital origin, but unknown derivation, are described. Several of these have been so large as to interfere with delivery of the fetus. Most often hepatic cysts are multiple and small. Such cysts are congenital anomalies, arising from dilatation of partially canalized bile ducts. About 25 per cent of patients with polycystic kidneys have hepatic cysts (p. 1024).

## POISONING

(ACUTE DIFFUSE HEPATIC NECROSIS, ACUTE LIVER ATROPHY, ACUTE YELLOW ATROPHY)

**Etiology.** Acute atrophy of the liver is a rare disease, usually fatal, in which there is an acute diffuse necrosis of the liver. Though the disease is commonly termed acute yellow atrophy, a red atrophy which is a later stage of yellow atrophy is also described. Different toxic agents are recognized as etiologic factors, such as phosphorus, arsenicals, chloroform, bismuth, trinitrotoluene, tetrachlor ethane and mushrooms (*Amanita phalloides*). Syphilis has also been known to cause hepatic necrosis. There is also a relation between infectious hepatitis and yellow atrophy. Selander reported that 3.4 per cent of a series of 1190 cases of infectious hepatitis progressed

to acute yellow atrophy. It is likely that predisposing factors such as malnutrition, concurrent illness and individual hypersensitivity are operative. The incidence is relatively high in tropical and subtropical countries.

**Clinical Manifestations.** The clinical picture is similar to, but more severe than, that of infectious hepatitis. Three stages of the disease are described, but, in some instances, fulminating hepatic necrosis without any prodromes leads to rapid death. The prodromal stage, consisting in constitutional disturbances (fever, headache, asthenia, articular pains) and gastrointestinal symptoms (anorexia, nausea and vomiting), is followed in six to fourteen days by the icteric stage. In one sixth of the reported cases icterus was the initial symptom. The jaundice fluctuates in severity, but is usually extreme. Hemorrhagic phenomena are especially common during the terminal stage, which is characterized by the occurrence of grave nervous symptoms. Increased muscular irritability is followed by increasing drowsiness leading to coma. Convulsions are uncommon.

The breath often has a characteristic odor, "fotor hepaticus." The liver may be enlarged initially, but usually shrinks progressively as the disease advances. The spleen is enlarged in almost all cases. All functions of the liver are depressed to low levels, and tyrosine is found in the urine.

**Treatment.** In most instances acute liver necrosis ends fatally. Owing to loss of most hepatic functions, replacement and supportive therapy is indicated; fluids, electrolytes, glucose and protein (plasma and serum albumin) should be supplied by parenteral means to supplement the oral intake. Potassium-containing foods or 0.5 gm. of potassium chloride (per day) should be given to provide the needs of a high carbohydrate intake. Large doses of vitamin B complex, vitamin K, liver extract and tocopherol should be given intramuscularly, and choline chloride is administered by gastric tube. One of the tetracyclines may be given intravenously. Corticosteroids have had no favorable effect.

## FATTY INFILTRATION

**Pathology.** Fatty infiltration of the liver results from deposition of dietary or mobilized tissue fat in the hepatic cells. Various lipotropic factors prevent the accumulation or accelerate the removal of excessive hepatic fat in the experimental animal. Choline and a large number of its chemical analogues in-

hibit the deposition of neutral fats and cholesterol esters and cause more rapid removal of these lipids from the livers of animals fed excessive fat. Choline also has an influence upon ketosis. Many proteins have a lipotropic action, probably due to specific amino acids. Thus methionine definitely has been shown to be lipotropic.

Fat is deposited in normal liver cells and, in larger amounts, in damaged liver cells in a variety of clinical conditions. Fatty infiltration of the liver occurs in many metabolic disorders such as obesity, starvation, galactosemia, diabetes mellitus and familial hyperlipemia. It is encountered frequently in chronic tuberculosis and osteomyelitis and occasionally after pneumonia. Large fatty livers occur in poisoning with phosphorus, phlorhizin, chloroform, alcohol, arsenic and mushrooms, and in severe anemic states in which it is assumed the liver is damaged by anoxia.

A familial occurrence of fatty liver was described by Bjorun. One of his patients showed beginning cirrhosis.

Fatty infiltration of the liver is a common secondary condition in childhood. Wollstein encountered it in more than half of a series of 345 consecutive autopsies.

**Clinical Manifestations.** Infiltration of the liver by fat is usually not directly responsible for symptoms or abnormalities in hepatic function. When hypoglycemia and ketosis are present, the hepatomegaly may be confused with glycogen disease. The usual clinical finding is hepatic enlargement, which may be extreme in some instances.

**Differential Diagnosis.** Fatty infiltration of the liver should not be confused with *fatty degeneration* of hepatic cells, in which pre-existent invisible cell lipids are altered chemically and become visible as fat droplets. In fatty infiltration the normal lipid content of the liver (3 to 5 per cent) may increase to 40 per cent. In fatty degeneration there is a change in the cellular lipids with an alteration in the normal proportion between hepatic cholesterol and other hepatic lipids, but no absolute increase of liver fat. Occasionally, with hyperlipemia, the Kupffer cells of the liver will phagocytize fat droplets and become swollen.

**Treatment.** Reduction of fat intake with a liberal allowance of protein would seem to be indicated. Beneficial effects have been described after administration of choline and its analogues (betaine), but are difficult to evaluate.

## THE GALLBLADDER

**Anatomy.** The gallbladder in the newborn infant is deeply embedded in the liver and usually does not reach the liver edge. The gallbladder is three times as long as it is thick. In the young infant it is tubular; it gradually assumes its pear shape in later infancy. In the adult the gallbladder is 8 to 11 cm. long. The volume is 3.2 ml. in the young infant, 40 ml. in the adult.

**Congenital Anomalies.** Congenital anomalies of the gallbladder, which are rare, include double gallbladder; bilobed gallbladder; diverticulum of the gallbladder; floating gallbladder, which is suspended from the liver by a mesentery and is freely movable; anomalous position of the gallbladder, which may be left-sided, intrahepatic and retrodisplaced; absence of the gallbladder without other anomalies of the biliary system or liver; and absence of the gallbladder with congenital atresia of the extrahepatic ducts.

### CHOLECYSTITIS

Inflammation of the gallbladder, though uncommon, is not as rare as it is generally thought to be. It may be due to a variety of bacterial infections, including typhoid fever. Migration of such intestinal parasites as *Ascaris* and protozoa in the child is ordinarily unaccompanied by inflammation, which is

common in the adult. The *symptoms* are nausea, vomiting, fever, abdominal distention and pain in the right upper quadrant. Since the disease is usually due to bacterial infection in children, sulfonamide and antibiotic therapy should be used before resorting to surgery. With advancing symptoms, however, surgery is advisable. The *diagnosis* is not easily made, since most pain in the right upper quadrant in children is not of gallbladder origin. In many instances a preoperative diagnosis of intestinal obstruction is made.

### CHOLELITHIASIS

Biliary calculi are infrequent in early life, but are more common than infection of the gallbladder. Calculi have been reported in still-born fetuses. Cholelithiasis in childhood is chiefly a complication of congenital hemolytic anemia in white children and sickle cell anemia in Negroes. Though the stones are composed almost entirely of the excessive blood pigment liberated by hemolysis, calcium is deposited in some, so that a shadow may be cast on the roentgenogram. The pure pigment stone without calcium casts no shadow and is demonstrable on the roentgenogram only by the use of gallbladder contrast medium.

## THE BILE DUCTS

### CYSTIC DILATATION

**Etiology and Pathology.** Choledochus cyst, or cystic dilatation of the common bile duct, is an idiopathic congenital condition. In 80 per cent of the recorded cases the patients are females less than ten years of age. Often there is no demonstrable mechanical obstruction. The dilatation is usually localized to the common duct, in contradistinction to the dilatation resulting from obstruction which involves the entire biliary tract and gallbladder. Occasionally the dilatation may involve the cystic and hepatic ducts. A choledochus cyst may grow to large dimensions; cysts with a capacity of 2 liters are recorded.

**Clinical Manifestations.** The clinical findings in choledochus cyst are pain, jaundice and abdominal tumor. The liver is often en-

larged and cirrhotic and is frequently infected. Fever occurs at times and is indicative of infection in the biliary tract or liver. The pain is in the upper abdominal or umbilical region and is usually "dragging." Jaundice is usually present. Exacerbations and remissions of symptoms are common.

**Treatment.** This is surgical. The operation of choice is a primary anastomosis between the biliary system and the intestinal tract. The results following operation are good.

### CONGENITAL ATRESIA

**Etiology.** Congenital obliteration of the bile ducts results from a maldevelopment of the biliary ducts. Inflammatory processes have been advanced as a theoretic cause, but careful study has failed to reveal evidence to

support it. In early fetal life the bile ducts are patent, but later become obliterated by epithelial proliferation and form solid cords. As normal development continues, the solid cords become canalized by the formation of vacuoles which coalesce, and the lumens of the ducts are thus re-established. An arrest in development at the solid cord stage would explain the congenital atresia.

**Pathology.** On postmortem examination the tissues are jaundiced, and there is usually ascites from portal obstruction. The firm liver has a nodular surface and may be two or three times its normal size; histologically, the findings are those of biliary stasis and biliary cirrhosis. If death occurs early, biliary stasis predominates; if late, cirrhosis is more prominent. The gallbladder may be absent or be represented as a canalized cord containing clear, thick mucoid material. At times it may be distended with "white bile," which is an accumulation of the secretion of its own mucosal glands. In obstruction of the common duct the gallbladder may be of normal appearance and contain bile, or it may be greatly distended with bile if the obstruction is low. The spleen is enlarged because of portal obstruction secondary to biliary cirrhosis. In cases of long duration the bones may show osteoporosis, a result of the poor absorption of calcium which is excreted.

The various anatomic malformations in this condition have been classified into the following groups by Ladd: (1) absence of the extrahepatic ducts; (2) atresia of the hepatic ducts; (3) atresia of the common duct; (4) a gallbladder represented by a moderate-sized cyst which is not connected with the common duct and in which there may or may not be any common or hepatic ducts; (5) a gallbladder which connects directly with the duodenum, but in which there are no ducts connecting the liver and gallbladder or the liver and intestine; (6) stenosis of the common duct due to plugging with inspissated bile, causing complete obstruction; (7) narrowing of the common duct, causing partial obstruction. In some instances there is absence of the intrahepatic ducts.

**Clinical Manifestations.** Jaundice is the outstanding manifestation. In most instances it is not discerned until two or three weeks after birth, though it may be apparent earlier. After its appearance the jaundice increases progressively without remission, and the infant assumes a deepening greenish bronze color. The olive-green component of the pigmentation results from deposition of biliver-

din, the oxidation product of bilirubin, in the tissues. The van den Bergh reaction is direct. The urine is intensely bile-stained and contains bile salts; since bile is excluded from the intestine, urobilinogen is not formed and is accordingly absent from the urine. The tears and saliva may be pigmented.

At times so-called liver breath, an odor resembling that of decaying liver tissue, is noted. The stools are abnormal before jaundice is conspicuous. Though the early meconium may appear normal, the stools are always putty-like in consistency and white or clay-colored, owing to their high content of fat and absence of pigment. In intensely jaundiced, and usually older, infants the stools may contain a low concentration of bile pigment derived from the secretions and desquamation of the bile-stained intestinal mucosa, so that a faint yellowish tinge is added to the predominant grayish color. There is, however, never the intermittent deeper staining with bile which is seen in the stools of many infants with biliary obstruction resulting from choledochus cyst, inspissation of bile or neonatal hepatitis. The liver is enlarged, and its firm, smooth edge may extend below the umbilicus. The spleen may be moderately enlarged. Ascites is frequently present.

The nutritional status of these infants, except for a reduced amount of subcutaneous fat, may remain surprisingly good for months, but slowness of movement and a lack of alertness are apparent in many of them. The appetite is good. Constipation is more frequent than diarrhea or vomiting. Deficiencies of the fat-soluble vitamins A, D, and K eventually develop. Protein metabolism is not disturbed. Carbohydrate absorption is normal, but the gradually developing cirrhosis of the liver interferes with hepatic glycogen storage and liberation, so that hypoglycemia may occur in older infants.

If obstruction cannot be relieved surgically, the prognosis is poor. Death was formerly due mainly to infection or hemorrhage. With the availability of antibiotics and vitamin K longer survival is being observed; one patient is known to have lived nine and one-half years.

**Diagnosis.** Congenital malformation of the bile ducts must be differentiated from numerous other causes of jaundice in early infancy. Elimination of conditions responsible for icterus during the first week of life, including physiologic jaundice, erythroblastosis due to RH, ABO and other rarer incompatibilities, and a group of less common disorders such

as sepsis, congenital syphilis, galactosemia and familial nonhemolytic jaundice with kernicterus, presents few difficulties. In these situations the jaundice is of the hemolytic type, characterized by elevation of indirect bilirubin. In atresia of the bile ducts the regurgitated bilirubin gives a direct reaction and is usually first evident as clinical jaundice after the first week of life. The acholic stools of biliary atresia are an additional differential point.

In addition to biliary atresia, clinical jaundice may appear in neonates in association with such conditions as neonatal hepatitis (type B), obstruction by inspissated bile in erythroblastosis fetalis or from unknown causes, rarely with prolonged physiologic jaundice, congenital and acquired hemolytic jaundice, syphilis and pressure occlusion of the biliary ducts by tumors and the like. Toxoplasmosis, infection with herpesvirus and galactosemia may produce jaundice in the early days of life.

Surgical exploration for atresia of the bile ducts is indicated when (1) bile is absent from the stools and duodenal secretions; (2) urobilinogen is absent from the urine; (3) the amount of direct-reacting bilirubin has increased progressively to high levels from an initial range of 5 to 10 mg. per 100 ml.; (4) the cephalin-cholesterol flocculation and thymol turbidity tests are negative; (5) there is no evidence of erythroblastosis fetalis.

Contrariwise, biliary atresia is unlikely and surgery may be deferred when (1) incomplete biliary obstruction is suggested by the finding of bile even in small amounts in the stools or duodenal contents and the urinary excretion of urobilinogen is normal; (2) erythroblastosis fetalis is indicated by an initial bilirubin level of 10 to 30 mg. per 100 ml. and by the finding of blood group incompatibilities; or (3) obstruction by inspissated bile of unknown etiology (type B viral hepatitis?) is suggested when serial determinations show a fluctuating bilirubin content instead of a progressively increasing one.

**Treatment.** Biopsy of the liver, either by laparotomy or by needle aspiration, is frequently required to differentiate biliary atresia from neonatal hepatitis or the inspissated bile syndrome. Needle biopsy requires familiarization with the technique, but is less traumatic than laparotomy. If laparotomy is performed, cholangiography with radiopaque solutions should take the place of manual exploration of the ducts, since the latter carries a high mortality rate in infants with hepatic

disorders. The various surgical procedures for establishing a pathway for bile into the intestinal tract are described by Gross. Not more than 16 per cent of infants with atresias are amenable to surgical repair.

Biliary obstruction resulting from inspissated bile has been relieved by duodenal intubation of 25 per cent magnesium sulfate and by the use of other cholagogues. The prognosis in infants with erythroblastosis is excellent; all of one group of twenty-three patients recovered completely. More than half of another group of thirty infants with obstruction due to inspissation of bile of unknown etiology recovered completely.

## THE PANCREAS

**Anatomy.** The pancreas originates from three separate outgrowths from the duodenum. The three segments fuse as the embryo develops, but anatomically the head, body and tail can be distinguished in the pancreas of the newborn infant, the head being pro-

portionately larger than in the adult. In the embryo the duct of Santorini runs from the separate posterior segment to the duodenum, and the duct of Wirsung drains the two anterior segments. As the three segments fuse, the two ducts become jointed at an acute

angle in the body of the pancreas, but maintain their separate openings into the duodenum; Wirsung's duct opens into the ampulla of Vater with the common bile duct, and Santorini's duct opens into the duodenum, somewhat closer to the pylorus.

The pancreas of the newborn infant is 4 to 5 cm. long and about 12 mm. thick, and weighs 2 to 3.5 gm. At one year of age it weighs about 10 gm., about 20 gm. at four to five years and 30 gm. at ten to twelve years. In the young adult it varies in weight from 66 to 102 gm.

In the newborn infant the islets of Langerhans are relatively more numerous in relation to the acinar tissue than in the adult. New islets appear until the child is about four years of age, when the acinar tissue begins to proliferate rapidly.

**Anomalies of the Pancreas.** Anomalies of the pancreas are rarely the cause of clinical disturbances. Absence of the pancreas has been noted in severe monster formation. Occasionally the tail of the gland has been bifid or the organ has existed as two separate glands with separate ducts to the duodenum. The pancreas may partially or completely surround the descending duodenum (annular pancreas) and cause acute or recurrent intestinal obstructions. Roentgenologic examination reveals dilatation of the first portion and collapse of the third portion of the obstructed duodenum. Accessory pancreatic tissues (pancreatic heterotopia) complete with their own small ducts have been discovered in the stomach, duodenum, jejunum and ileum. Ectopic pancreatic tissue, in rare instances, has served as the lead point of an intussusception. Pathologic changes in aberrant pancreatic tissue include inflammation with erosion of the intestinal mucosa leading to ulceration and hemorrhage, fat necrosis and single or multiple islet cell tumors causing hyperinsulinism.

Deviations of the pancreatic ducts of Wirsung and Santorini from their usual anatomic arrangements are of little clinical significance. Congenital stenosis of the pancreatic ducts has been described as a cause of meconium ileus.

Congenital hypoplasia of the exocrine part of the pancreas associated with steatorrhea and undernutrition has been recorded. Absence of fibrosis, of dilatation of the ducts and of characteristic pulmonary changes differentiates this congenital defect from fibrocystic disease of the pancreas.

**Physiology of the External Secretory Glands of the Pancreas.** The secretion of pancreatic juice is regulated by both nervous and hormonal influences. Parasympathetic nervous (vagus) stimulation produces a small flow of juice of high protein and high enzyme content. This so-called cephalic phase of pancreatic secretion is probably a reflex from the oral cavity through the vagus nerve resulting in "psychic" secretion. It is abolished by atropine. Various drugs which stimulate the vagus mechanism—pilocarpine, acetylcholine, acetyl-beta-methylcholine chloride (Mecholyl chloride), physostigmine and neostigmine—produce an increased concentration of enzymes without much increase in volume of the pancreatic juice. Stimulation of the splanchnic nerve (sympathetic) causes increases in the amounts of pancreatic juice and of trypsin secreted per unit of time. Various phenomena inhibit pancreatic secretion reflexly, e.g., overdistention of the stomach, vomiting, and emotional reactions such as rage and mental discomfort. Vasoconstriction of the pancreatic blood vessels decreases or abolishes pancreatic secretion.

Secretin, a hormone liberated by the mucosal cells of the upper intestinal tract, is transported by the blood to the pancreas, where it incites the flow of a thin watery juice of high bicarbonate and low enzyme concentration. Contact of the intestinal mucosa with a variety of substances (hydrochloric acid, proteins, fats, carbohydrates and digested foodstuffs such as peptones and amino and organic acids) leads to secretion of secretin. The products of fat digestion increase pancreatic secretion by stimulation of the vagal endings in the duodenum. The generalization is made that the vagus regulates the enzyme content of pancreatic juice, and secretion regulates the volume and sodium bicarbonate content. Fractionation of the crude extract of duodenal mucosa from which secretin is prepared yields pancreozymin, along with several other hormones, which stimulates pancreatic excretion of viscid juice with high enzyme and low bicarbonate content. However, there is no evidence that it is secreted into the blood by living intestinal mucosa.

Pancreatic juice, a clear or slightly opalescent alkaline (average pH, 8.3) fluid, contains mucus, mucoproteins and three enzymes, usually designated amylase, lipase and trypsin. Actually there are two amylases, alpha and beta; one lipase, and four prote-

olytic enzymes. Starches are split to maltose by the amylases. An intestinal enzyme, maltase, completes the hydrolysis of maltose to glucose. Secreted in an inert form, pancreatic lipase is activated by bile salts and other substances, including bacteria, and converts neutral fat into fatty acid and glycerol.

The proteolytic enzymes are secreted as inactive substances combined with specific enzyme inhibitors. Trypsin by its enzymatic action and the intestinal hormone enterokinase, by antagonizing the inhibitors, activate the proteolytic enzymes. Trypsin and chymotrypsin, each acting separately, digest proteins to peptides, which are split to amino acids by pancreatic and intestinal carboxypeptidases (erepsins).

Secretin and the pancreatic enzymes, trypsin, lipase and amylase, are present in the newborn infant and are probably present in the fetus as early as the fifth month, the proteolytic activity being responsible for the liquid state of the meconium in the intestinal tract of fetuses.

TESTS OF PANCREATIC FUNCTION

Studies of Pancreatic Enzymes Obtained by Duodenal Intubation. The fluid obtained from the duodenum is normally clear and watery, and may be colorless or varying shades of yellow, depending on its bile content. It is usually alkaline with a pH of about 8.3, but may vary from pH 6.5 to 9. The amount of fluid varies from time to time in the same person, but there is usually an increase with age. Infants under two months of age yield 1 to 5 cc. per hour, averaging 3 cc.; infants one year of age about 6 cc.; older children, as much as 48 cc. In children with chronic nutritional disturbances or idiopathic celiac disease there is no change in the appearance of the fluid, although larger volumes are at times obtained from children with celiac disease. The fluid obtained from patients with pan-

creatic fibrosis is diminished in volume and is thick and sticky. The mucoprotein fraction of normal duodenal fluid is completely soluble in water, whereas in patients with cystic fibrosis a considerable portion of it is water-insoluble.

The enzyme activities of the duodenal fluids of normal infants and children have been quantitated by Andersen and by Farber and his co-workers. The values in Table 90 are typical findings. The enzyme values were all within the normal range in patients with nutritional disturbances. With hypoproteinemia, as in kwashiorkor, there may be an absence of pancreatic enzymes, presumably due to lack of amino acids for formation of enzymes by the acini. In idiopathic celiac disease and in chronic diarrhea there is a significant depression of amylase concentration in infants older than six months of age, and in marasmic infants there is a depression of the level of all three enzymes. Agren, Lagerlof and Berglund pointed out the frequency with which pancreatic injury results in a reduction in the secretion of amylase alone and suggest that this represents the mildest form of damage in pancreatitis. In patients with pancreatic fibrosis all enzyme activity is commonly absent or, when present, is very low. Andersen has suggested a simple test for trypsin activity as a diagnostic aid for pancreatic fibrosis. This may be an adequate index of total pancreatic enzymatic activity in most instances, but selective deficiency of pancreatic enzymes has been observed in about 10 per cent of cases, and an occasional patient may show normal activities of all three enzymes.

Intravenous administration of secretin results in an increased volume of more alkaline duodenal fluid. Though there is some increase in amylolytic and lipolytic activity in normal persons after stimulation of secretin, there is no increase in tryptic activity. In patients with pancreatic fibrosis the volume of duodenal fluid is not increased after secretin injection, and the activity of trypsin is unchanged; that of lipase and amylase may be slightly decreased at times.

Studies of Pancreatic Enzymes in Stools. In the feces of the normal person, amylase and trypsin, but not lipase, are demonstrable. Though the adult with complete occlusion of the pancreatic ducts shows an absence of fecal amylase, the extreme fluctuations

Table 90. Pancreatic Enzymes in Duodenal Juice of Normal Infants and Children\*

From D. Andersen: Am. J. Dis. Child., Vol. 63.  
\* Enzyme activities expressed in units per hour rather than per volume of duodenal fluid give a more accurate picture of normal values, since the enzyme content is fairly constant with time, but varies inversely with the rate of flow (dilution) of pancreatic juice. Farber, taking cognizance of this fact, expressed the values in terms of units per hour.

in the normal person make fecal quantitation of enzyme activity un dependable.

*The demonstration of trypsin in the stools by its ability to digest the gelatinous coating of photographic film is a simple and crude screening test for patients with cystic fibrosis of the pancreas.* Its value as a diagnostic test is not great, because proteolytic activity may be present in stools of bacterial origin (gelatinase) or due to ingestion of honeydew melon, pineapple or pancreatin. Also normal amounts of trypsin may disappear completely during passage through the intestinal tract. The accuracy of this test may be improved by special dilution techniques or by adding soybean trypsin inhibitor, which abolishes pancreatic trypsin activity, but does not affect bacterial gelatinases.

**Studies of Pancreatic Enzymes in the Blood and Urine.** Normally, slight lipase and amylase activity is present in blood serum. In experimental and clinically acute inflammatory disease of the pancreas and in acute obstructions of the pancreatic ducts in adults there is regurgitation of pancreatic juice into the blood stream from ruptured small pancreatic canaliculi with resultant elevation of serum lipase and amylase. Elevated values are encountered a few hours after the onset of pancreatic inflammation; they reach a maximum in forty-eight to seventy-two hours and return to normal in ten to fourteen days. Salivary ptyalin may regurgitate into the blood and add to its amylolytic activity, e.g., in mumps.

The urinary amylase, derived from the blood, rises after pancreatic inflammation and reaches a peak in thirty-six to forty-eight hours, subsiding to normal in three to four days. Urinary amylase is increased in children with acute pancreatitis.

**Studies of Absorption of Fat from the Intestinal Tract.** The study of the changes in the blood fat levels after oral administration of fat (fat tolerance tests) is useful in demonstrating poor absorption of fat. A low fat tolerance curve is encountered in pancreatic achylia, but is more frequently the result of a variety of nonpancreatic conditions that cause poor intestinal fat digestion or absorption.

**Fat tolerance test.** After the oral administration of 2 gm. of fat per kilogram of body weight the normal child shows a rise in total blood fat of 200 mg. per 100 ml.; the elevation in the blood of the celiac patient does not exceed 50 mg.

**Vitamin A tolerance test.** After an oral dose of 7000 international units of Vitamin A (as halibut liver oil) per kilogram of body weight, normal children show a rise of 100 units per 100 ml. of blood in two to six hours. Children with celiac disease, though they have normal fasting vitamin A blood concentrations, exhibit only small increases of 8.2 to 26.5 international units in the tolerance test. Such children show impaired absorption if vitamin A is administered in either the ester or alcohol form; patients with cystic fibrosis of the pancreas can absorb the alcoholic form of vitamin A, but not the esterified compound.

**Fat absorption tests using iodized oil (Lipiodol).** Qualitative tests for iodine in varying dilutions of urine collected twelve to eighteen hours after oral ingestion of Lipiodol (5 to 10 cc., depending upon weight) are useful screening procedures for fibrocystic disease. A positive test for iodine in urine diluted 1 to 4 or greater probably excludes this dis-

order as a diagnosis. No inferences may be drawn from a negative test.

Quantitative iodine estimations on urine specimens taken at six, twelve and eighteen hours after ingestion of Lipiodol show differentiations between normal and abnormal values. The values for iodine in normal urine range from 140 to 340 mg. per 100 ml.; in celiac disease they do not exceed 120 mg., and in fibrocystic disease are below 40 mg. per 100 ml.

**Absorption of Protein Products from the Intestinal Tract.** The extent of protein digestion and absorption is indicated by the rise in blood amino acid concentration after a protein test meal. One such test measures the blood proline level two hours after feeding casein or gelatin (1.5 gm. per kilogram). The level in normal infants rises from the basal range of 5 to 35 micrograms per 100 ml. to values ranging from 100 to 120 micrograms. Patients with cystic fibrosis show no increase.

**Analysis of Stools for Undigested and Unabsorbed Food.** The appearance of excessive amounts of fat, carbohydrate (starch) or protein in the stool may be indicative of poor digestion resulting from pancreatic insufficiency or other causes, or from poor absorption from the intestinal tract. Estimations of fecal starch and fat content are commonly used in the study of children with the celiac syndrome.

**Estimation of fecal starch.** Undigested vegetable cells containing starch are present in normal stools. Recent studies indicate that an increased amount of extracellular starch, formerly considered an abnormal finding indicative of starch intolerance or malabsorption, is common to all diarrheal states, and is an occasional finding in normal children.

**Estimation of fecal fat.** Steatorrhea cannot be determined by inspection of the stool, since a fatty stool may appear normal, and at times a typically foul, frothy stool suspected of containing excessive fat may have a normal fat content.

Microscopic examination of stool specimens stained with scharlach R or Sudan IV is useful as a screening method. If, while the patient is on a normal diet, no fat is visible, the presence of steatorrhea can be ruled out. Conversely, the detection of large amounts of fat is significant.

Quantitative estimation of the average daily fecal fat excretion is an objective index of the presence or absence of steatorrhea. In normal infants this value does not exceed 3 gm. a day. The percentage of ingested fat which is absorbed is an even better criterion for steatorrhea.

Owing to the many factors responsible for the presence of an excess of fat in the stools, the following classification may be helpful in the evaluation of this finding.

## CAUSES OF STEATORRHEA

### Poor Digestion of Fat

1. Exclusion of bile from the intestine in obstructive jaundice caused by  
Congenital obliteration of bile ducts  
Choledochal cysts  
Viral hepatitis, and the like
2. Exclusion of pancreatic juice from the intestine caused by

- Cystic fibrosis of the pancreas
- Obstruction of ducts by *Ascaris*
- Starvation and protein-deficient diets in infants; atrophy of acini with decreased secretion of enzymes (e.g., kwashiorkor)
- Congenital hypoplasia of exocrine pancreatic glands
- Congenital cystosis of the pancreas

#### Poor Absorption of Fat

1. Excessive formation of insoluble soaps caused by Excessive intake of alkaline earths, such as calcium and magnesium
2. Excessive intake of fat containing long-chain saturated fatty acids, e.g., tripalmitin and tristearin (short-chain unsaturated fatty acids favor absorption)
3. Diseases and defects in intestinal wall caused by Resections and fistulas of intestine  
Regional enteritis  
Amyloid disease  
Scleroderma
4. Obstruction of intestinal lymphatics caused by Tuberculosis

- Hodgkin's disease
- Intestinal lipodystrophy (Whipple's disease)
- Lymphosarcoma and lymphadenoma

5. Disturbances of salt and water metabolism (e.g., dehydration and adrenal insufficiency impair the absorption of neutral fat, which is normally absorbed when the particle size is smaller than 0.5 micron in diameter)
6. Defective absorption of obscure mechanism caused by  
Celiac disease  
Sprue  
Infestation with *Giardia intestinalis*

#### Combination of Poor Digestion and Poor Absorption of Fat

1. Increased motility of small intestine in Diarrhea of any kind  
Intestinal allergy (when edema of intestinal wall may be an additional factor)  
Stenotic lesions of small intestine  
Gastrocolic fistula  
Malrotation of intestinal tract

## CELIAC DISTURBANCES\*

In a classic paper entitled "On the Coeliac Affection," Samuel Gee in 1888 vividly described the clinical picture of a state of chronic nutritional failure in infancy and childhood. The fully developed case is characterized by (1) pale, bulky, offensive stools; (2) abdominal distention; (3) wasting, which may be extreme; (4) stunting of growth, which may be severe enough to be termed infantilism; (5) severe anorexia and other nervous symptoms; and (6) clinical evidence of vitamin and mineral deficiencies.

Since this pattern of clinical findings may result from a variety of disturbances, it is termed the celiac syndrome. The more or less clearly defined entities belonging to this group are (1) true or idiopathic celiac disease, also called the malabsorption syndrome, a chronic disorder of intestinal assimilation of unknown nature, apparently hereditary in origin, which expresses itself in various patterns of nutritional disturbance and failure; (2) celiac syndrome resulting from mechanical obstruction of the pathways of digestion and/or absorption; (3) pancreatic insuffi-

ciency (cystic fibrosis of the pancreas); (4) severe dietary deficiency (starvation, kwashiorkor); (5) gastrointestinal allergy; (6) chronic intestinal infection (bacterial, parasitic, viral).

### TRUE OR IDIOPATHIC CELIAC DISEASE

(MALABSORPTION SYNDROME, CHRONIC IDIOPATHIC STEATORRHEA, GEE-HERTER DISEASE, HEUBNER-HERTER DISEASE, GEE-THAYSEN DISEASE, CHRONIC INTESTINAL INDIGESTION)

Idiopathic celiac disease is a chronic disorder of infants and children in which intestinal malabsorption, as evidenced by steatorrhea with varying degrees of losses of other nutrients, is prominent. The basic defect is obscure; a familial incidence suggests an underlying constitutional peculiarity, possibly of genetic origin. The proteins (glutens) of wheat, rye and oats are especially conspicuous as triggering agents, causing a gradual or acute increase in the manifestations of celiac disease in most patients. The deleterious action of wheat gluten is apparently a toxic one, rather than an allergic reaction, and is produced by its gliadin fraction. Ingestion of wheat or purified gliadin results in increased concentrations of blood glutamine in celiac patients, but not in normal controls. This phenomenon

\* Though evidence of pancreatic involvement in the various forms of the celiac syndrome is lacking except in the cases of cystic fibrosis of the pancreas and of congenital obstruction of the ducts of Wirsung and Santorini, the other clinical forms are included here in order to avoid unnecessary repetition in the general description of the symptom complex if they were located in other sections of the book.

has been made the basis of a gliadin tolerance test.\*

In one patient reported by Davison, beta lactoglobulin, one of the two whey proteins of milk, evoked steatorrhea, while ingestion of wheat gluten produced no harmful effect. In another child celiac disease was apparently associated with absence of bile salts, and in another case milk fat produced the malabsorption syndrome.

Parenteral infection, often of trivial degree, is a harmful stimulus in most children with celiac disease, and, in many, emotional and psychic disturbances lead to exacerbations of the disorder.

Andersen has designated as starch intolerance a mild disorder which she believes is a less severe form of celiac disease, characterized clinically by chronic and recurrent diarrhea and abdominal distention, with little evidence of malabsorption or malnutrition. However, other clinicians with experience in idiopathic celiac disease consider it to be a constitutional type of chronic nonspecific diarrhea associated primarily with water loss in the stools.

**Incidence.** There are no adequate data of the incidence, but inclusion of the milder forms of the disease in the clinical entity has made the disorder less rare than when only the severe forms were recognized. The disease has been seen in white children of almost all national origins; it is uncommon in the Negro race and unrecorded in Orientals. Both sexes are equally affected.

The occurrence of the disease in twins, fraternal and identical, and the numerous instances of multiple cases in one family speak for the inheritance of an unknown constitutional defect responsible for the disorder, apparently as a dominant character. Variable penetrance and expressivity of this genetic trait may account for the differing degrees of severity of the disease and the age at which it becomes manifest. It is also possible that the disease is inherited as a subclinical or very mild trait and is modified by extrinsic factors such as infection, dietary deficiency or psychic trauma, acting as trigger mechanisms, so that it becomes clinically evident at different ages, but usually within the first few years of life, and in varying degrees of clinical severity. The similarity between idiopathic celiac disease and sprue which occurs

in adults was first indicated by Gee. It would appear that the celiac state in the ages from five to twenty-five years may exist in a state of clinical remission. It may remain so or become reactivated to appear as sprue. The occurrence of sprue and celiac disease in different members of the same family is another way in which the relationship of the two conditions is expressed.

**Pathology.** The anatomic changes found in the rare postmortem examinations of patients with celiac disease are those resulting from (a) severe malnutrition, e.g., a small fatty liver, depletion of glycogen, atrophy of the body fat and lymphoid tissue; (b) secondary deficiency disease, chiefly rickets, but also scurvy, hypoprothrombinemia and hypoproteinemia.

**Clinical Manifestations.** *Severe form of idiopathic celiac disease (idiopathic steatorrhea).* The full-blown clinical picture of severe idiopathic celiac disease is most frequently seen during the second year of life. Careful inquiry, however, into the histories of such children reveals that the disease may begin insidiously or gradually with digestive disturbances at six to twelve months of age. During the evolutionary period, episodes of diarrhea accompanying and persisting after respiratory tract infection may occur at widely separated intervals. At times there may be alternating periods of constipation and diarrhea. The child may show marked loss of appetite with resultant failure of growth. Changes in behavior and disposition, usually marked by increasing irritability, are prominent. The disease is not seen in infants during breast feeding, and rarely appears within six months after they have been weaned.

**WASTING AND RETARDATION OF GROWTH AND DEVELOPMENT.** There is a decided loss of weight, most marked in the limbs and especially apparent in the buttocks, groins and axillary folds. The wrinkled skin of the flattened buttocks and groins may hang in loose folds. In contrast, the face, even in advanced cases, may be full and plump. Though the complexion is usually anemic or sallow, with dark rings or puffiness under the eyes, there is often a red flush on the cheeks. The sad, fretful expression, the plump face with red cheeks surrounded by sallow skin, and the shining bluish scleras produce an almost characteristic facies in children with celiac disease. There are marked, often daily, fluctuations in weight. Usually after mild respiratory or enteric infections, but at times with

\* Blood glutamine levels determined at one, two, three, four and five hours after ingestion of 350 mg. of gliadin per kilogram of body weight increase 40 per cent or more in patients with celiac disease.

no obvious antecedent, watery diarrhea and vomiting occur with resultant dehydration and acidosis, the so-called *celiac crisis*. This may be so severe as to result in death if not properly treated.

Retardation in growth involves height and weight; in severe cases a child three to four years of age may correspond in size to an infant one year of age. There is often great delay in the appearance of the epiphysial centers of ossification. Dentition is often delayed, and, in the rare instances of celiac disease in older children, puberty is also delayed.

**ABDOMINAL DISTENTION.** The abdominal enlargement is primarily caused by distention of a hypotonic intestinal tract by gas and fluid; relaxation of the abdominal musculature is also a contributory factor. Abnormalities in gastrointestinal motility have been noted in roentgenologic examinations, but are not characteristic.

**NERVOUS AND PSYCHOLOGIC SYMPTOMS.** There are profound changes in the behavior pattern with active celiac disease. Anorexia is a prominent symptom, at times culminating in refusal of all food, but more often expressed as a capricious appetite. The ill humor and moodiness, the bursts of temper and hysterical behavior, alternating with periods of great timidity, make these children a trial to even the most patient and loving parent. Sleep is often restless, with frequent grinding of the teeth, outcries and, not infrequently, night terrors and somnambulism. Vasomotor symptoms, such as excessive sweating and cold extremities, are frequent. With clinical improvement these abnormalities disappear. Owing to the combination of infantilism with a degree of intelligence which more closely parallels the child's age, the child is likely to appear precocious and unusually attractive during recovery.

**SYMPTOMS RESULTING FROM DIETARY DEFICIENCY.** The diarrhea and impairment of intestinal absorption, combined with an unbalanced diet, result in various dietary deficiencies, including those of specific vitamins.

**SYMPTOMS RESULTING FROM POOR ABSORPTION OF FAT.** The character of the stools varies with the severity of the disease and the nature of the diet. The classic celiac stool is a constant finding in the untreated patient of long standing and reappears during exacerbations resulting from an infection or dietary indiscretion. The typical celiac stool is bulky, weighing 100 to 1000 gm. as compared to a stool of normal weight of 40 to 80 gm.

Usually there is also an increased number of stools. The celiac stool is loose; during the periods of watery diarrhea accompanying celiac crises its water content may exceed 95 per cent. The stool is mushy, pale and frothy and, in addition, foul-smelling. At times it contains blood and excessive mucus, usually the result of a complicating enteric infection.

Removal of gluten (gliadin) from the diet usually causes disappearance of the frothiness and a decrease in the size of the stool, but it continues to be bulky and pale. With clinical improvement the stool may be formed and of normal color and at times become so hard as to cause constipation. Even during these periods it may contain excess fat.

On a mixed diet containing at least 20 gm. of fat the dried feces of a normal child contain 1.5 to 3 gm. of fat daily, and values above 4 gm. daily are abnormal. The stool of the patient with severe celiac disease contains more than this amount. The patient with celiac disease, however, absorbs a considerable portion of his ingested fat (from 65 to 80 per cent as compared to 90 to 98 per cent of intake in the normal child). The percentage of fat absorbed by the celiac patient is fairly constant with all levels of fat intake, so that a high intake is accompanied by an absolute increase in the amount of fat absorbed. The excess fecal fat is largely split fat, i.e., free fatty acids and soaps.

In the celiac patient there is no impairment in the digestion of fat, since the bile acids and pancreatic lipase are present in adequate amounts. Poor fat absorption is reflected in the low tolerance curves for olive oil, butter fat, vitamin A and Lipidol. Fasting blood vitamin A levels are usually within normal limits. There is, however, a great reduction and at times absence of the fat-soluble serum carotenoid pigments (the precursors of vitamin A), as is the case in any condition associated with steatorrhea.

**IMPAIRED CARBOHYDRATE ABSORPTION.** This is responsible for low oral glucose tolerance curves; the blood sugar rarely rises more than 40 mg. per 100 ml. in an active case. The intravenous glucose tolerance curves and the epinephrine tolerance tests are within the normal range, indicating that carbohydrates are handled normally after absorption from the intestinal tract. The absorption of d-xylose, estimated from the five hour urinary excretion test, is a more exact measure of carbohydrate absorption since it is not altered by the hepatic, endocrine or renal factors

which influence glucose. It is of value in demonstrating poor carbohydrate absorption in celiac disease.

**PROTEIN DEFICIENCY SYMPTOMS.** Moderate hypoproteinemia is a common finding in well developed celiac disease. Both serum albumin and globulin are usually reduced, but in some instances only the albumin level is depressed, at times to edema-producing levels. There is no impairment of protein digestion in celiac disease. Protein absorption is apparently normal during nondiarrheal periods.

**SYMPTOMS CAUSED BY LOSS OF MINERALS IN THE STOOL.** Loss of large amounts of dietary minerals in the stools has been ascribed to the formation of insoluble soaps. Although the amount of mineral loss varies directly with the severity of the disease, it does not bear a linear relationship to the fecal fat content.

The effects of loss of calcium have been indicated. Anemia results from loss of iron. Sodium and potassium are poorly retained; extensive losses of water and of these minerals during celiac crises may result in dehydration, shock, acidosis and symptoms of hypokalemia.

**Starch intolerance: The mild uncomplicated form of celiac disease (constitutional chronic nonspecific diarrhea).** The relationship of this relatively common mild disorder to the more severe classic form of idiopathic steatorrhea has not been established. The diagnosis is based on the finding of abundant extracellular starch granules in the feces after the feeding of starch or especially during relatively asymptomatic periods of infants and children with recurrent chronic diarrhea, abdominal distention and growth failure. Andersen has proposed that such cases represent a mild uncomplicated form of idiopathic steatorrhea. Steatorrhea and other findings of the more severe form of celiac disease are considered transitory complications, resulting from multiple nutritional deficiencies superimposed on the milder disturbance.

Many clinicians regard this relatively mild disorder not as a variant of the celiac syndrome, but rather as a familial type of chronic diarrhea due to hypermotility of the colon. Infectious episodes, emotional disturbances, food allergies and anatomic defects act as trigger mechanisms to the hyperirritable colon in instituting diarrhea. Davison has demonstrated considerable amounts of extracellular starch granules in the feces of normal children, and starch granules are regularly pres-

ent in diarrheal stools. Thus amyloorrhea would appear to be a manifestation of large bowel irritability rather than of starch intolerance.

**Prognosis.** The high mortality of former years (15 per cent in England before 1938) was in part a reflection of the inclusion of cystic fibrosis in the single category of celiac disease. With better understanding of dietary management and parenteral fluid therapy, and effective control of infection by antibiotics, death from celiac disease is unusual; improvement and clinical recovery are the rule. Recovery is a protracted, intermittent process: disappearance of the signs and symptoms usually occurs six to twenty-four months after beginning therapy, the time being conditioned by the duration of symptoms before treatment. The course is characterized by periods of rapid improvement, and equally rapid exacerbations often preceded by infection, dietary lapse or psychic disturbance and at times without apparent cause. Improvement usually proceeds according to the following pattern: vomiting, diarrhea, anorexia and edema disappear first; then the stools decrease in amount and fat content, assuming a more normal color and consistency. As appetite increases, the child's behavior and sense of well-being improve, and weight gain occurs, followed by resumption of growth in height. Anemia may be stubborn. It is felt that clinical recovery is a state of remission of the disorder; since celiac disease is a constitutional defect, it is doubtful whether actual cure takes place. In support of this viewpoint are the abnormal laboratory findings in "normal" patients, gliadin tolerance curves, decreased fat absorption, and the occasional recurrence of the disorder as sprue during adult life.

**Treatment.** Ignorance of the basic metabolic error precludes an etiologic approach to treatment, which is essentially empirical. The various dietary regimens effective in celiac patients have derived from clinical experience. Unfortunately, at times, this has resulted in undue preoccupation with the effect of treatment on the stools, to the neglect of the patient. Successful management is not as dependent upon strict adherence to a rigid dietary plan as it is upon judicious supervision of the diet by an informed physician guided by the child's growth responses, his altered behavior patterns and the emotional difficulties and anxieties of the parents.

The diet chosen at the beginning of treatment will depend upon the patient's condition. In deteriorated celiac patients or in those

with questionable powers of intestinal assimilation it is well to begin cautiously with skimmed or protein milks sweetened with glucose, sucrose or banana powder. Meats, eggs, cheese, fruits, vegetables and fruit juices are added singly at two- to three-day intervals, and a full but gluten-free diet may be achieved after two to three weeks. If gluten is strictly avoided, most patients will thrive on a diet which is normal in all other respects; in most instances the child should not eat with the parents. A properly constructed celiac diet is based upon the following considerations:

1. *An adequate caloric intake* to provide for both the repair of the deficit and the maintenance of normal growth and to compensate for continued fecal losses of nutrients. About 15 to 25 per cent more than the calculated requirement for expected weight and height may be necessary.

2. *Optimal amounts of protein*, usually ranging from 6 to 8 gm. per kilogram of body weight per day and at times up to 10 gm. Protein may constitute as much as 25 per cent of the total calories and be derived from milk, cheese, meat, fish, poultry and eggs. In the child with edema associated with hypoproteinemia it is wiser to remedy the plasma protein deficit by transfusions of serum albumin, plasma or blood than to rely on the slow regeneration from dietary protein.

3. *Carbohydrate in all its forms*. This is well tolerated and should furnish about half of the daily caloric intake. There is no convincing proof that disaccharides are not as well tolerated as the monosaccharides. The deleterious effects attributed to polysaccharides (starches) have been shown to be due to *gluten*. By excluding gluten-containing grains such as wheat, rye and possibly oats and barley from the diet, starches such as rice, corn, potato, buckwheat and pure wheat starch (prepared by removing gluten from wheat) may be given without ensuing difficulty.

4. *Normal amounts of fat* are tolerated by most celiac patients receiving a gluten-free diet. The percentage of fat absorbed by celiac patients is relatively constant at different levels of intake. As in any other patient with gastroenteritis, dietary fat is restricted in the acutely ill celiac child or following a crisis, and is reintroduced gradually as the ability to assimilate it is regained. Since unsaturated and short-chain fatty acids are absorbed better than other fats, replacement of some of the butter, margarine and animal fat by

vegetable oils (olive, corn, peanut, soybean, cottonseed) may be advantageous.

5. *Supplements of vitamins and minerals* in generous amounts for every celiac patient. From 15,000 to 25,000 units of vitamin A and 2000 to 6000 units of vitamin D are provided daily in water-miscible preparations. Vitamins of the B complex should be included in the polyvitamin preparations in doses two to three times the suggested prophylactic levels. From 75 to 100 mg. of ascorbic acid is an adequate daily allowance. It is well to add 0.5 to 1.0 gm. of iron as ferrous sulfate daily, and, if macrocytic anemia is present, supplementation with folic acid and vitamin B<sub>12</sub> would seem to be indicated. Parenteral administration of liver extract or vitamin B complex, once strongly advocated, may be useful during episodes of severe illness; otherwise it is unnecessary.

To assure rigid exclusion of gluten from the diet it is important to list for the parents the food products which contain wheat or rye in any form whatsoever, including gravies, processed meats, meat loaf, puddings and "breaded foods."

To satisfy the frequent craving for bread or cookies, substitutes made from pure wheat starch or buckwheat flour may be prepared.

Awareness and sympathetic understanding of the many psychologic difficulties associated with this chronic disorder are important for the successful management of the patient and his family. Parental anxieties expressed as feelings of guilt and ambivalence toward the child, overprotection and undue concern with the character of the stools are some of the problems with which the physician will have to cope.

The acute episodes of severe diarrhea, initiated most often by parenteral infections or dietary indiscretion, are termed celiac crises. They are especially common in hypoproteinemic patients and require prompt and vigorous treatment. The general principles of fluid and electrolyte replacement and maintenance therapy are utilized to overcome the dehydration, shock, hypoproteinemia and electrolyte imbalances (acidosis, hyponatremia and hypokalemia). If tetany occurs, calcium should be given until the serum calcium is restored to a normal level. Since infection is most often present, suitable antibiotic therapy should be provided.

Adrenal steroid therapy produces dramatic remissions in celiac disease. It may be extremely useful as emergency treatment during celiac crises, or in the management of severe

cases in which there is hypoproteinemia and edema. It is not a cure, since there is a relapse when the therapy is withdrawn.

#### **CELIAC SYNDROME SECONDARY TO OBSTRUCTION OF DIGESTIVE AND ABSORPTIVE PATHWAYS**

*Chronic, mechanically obstructive processes* involving the small intestine or the intestinal lymphatics may be responsible for impairment of absorption, especially of fat. Large fecal losses of unabsorbed fat and protein with their resultant clinical sequels occur when food is excluded from the small bowel by fistulous connections between the stomach and large intestine. Lesions of this sort are extremely rare. Disturbances of intestinal motility resulting from the presence of stenotic areas in the small intestine, from regional ileitis and from malrotation of the intestines have also led to steatorrhea and other symptoms of the celiac syndrome in infants. Surgical correction of such defects has resulted in disappearance of symptoms.

It has been suggested that heavy infestation of the wall of the small intestine by *Giardia intestinalis* acts as a barrier to absorption of fat. Véghelyi reported the disappearance of steatorrhea when giardiasis was cured by the administration of Atabrine (p. 614).

*Intestinal allergy* may be responsible for steatorrhea in infants. The sensitized small intestine reacts to contact with the offending antigen by an increase in motility and by the development of edema of the mucosa, so that poor intestinal absorption is a sequel. When cow's milk is the allergen, chronic diarrhea persists until the milk is replaced by a soy bean or casein hydrolysate substitute.

Since the largest part (60 per cent or more) of absorbed fat reaches the general circulation by way of the lymphatics, *chronic obstruction of the intestinal lymphatic pathways* leads to steatorrhea. The sprue syndrome in adults and the celiac syndrome in children have been observed as accompaniments of tuberculous mesenteric adenitis.

Among the nontuberculous conditions of the mesenteric nodes leading to steatorrhea, Whipple described a syndrome which he named intestinal lipodystrophy, to which the names "lipophagia granulomatosis" and "mesenteric chyladenectasis" have also been applied. This condition, occurring chiefly in adults, is characterized by inflammatory changes in the mesenteric lymph nodes, which are engorged with fat and contain foamy macrophages laden with glycoprotein.

The etiology of the disorder is obscure, but the occurrence of polyserositis and an increased glycoprotein content of the blood indicates that the lesions in the mesenteric nodes are only part of a generalized disturbance. Infiltration of the mesenteric nodes by Hodgkin's disease, lymphosarcoma and lymphoma is an uncommon cause of intestinal malabsorption. Whether acute mesenteric adenitis causes transient disorders of fat absorption is unknown.

#### **CYSTIC FIBROSIS OF THE PANCREAS (MUCOVISCIDOSIS)**

This is a congenital disease in which the clinical evidences of the celiac syndrome, resulting from pancreatic exocrine insufficiency, are combined with severe pulmonary disease.

Genetic studies indicate that pancreatic fibrosis is inherited as a mendelian recessive character. It has been estimated that one in fifteen to one in fifty in the population carries the gene responsible for the defect. Both parents must be carriers; the probabilities are 25 per cent than any one child will have the disease and 50 per cent that he will be a carrier.

**Etiology.** The disease is uncommon but not rare. Its incidence in the general population has been estimated to be in the range of 1:1000 to 1:10,000. It is encountered in 2 to 5 per cent of autopsies on infants and children. Both sexes are affected equally. Geographically, the disorder is widespread, although it is rarely seen in Negro infants and never in mongoloids.

**Pathology.** The characteristic lesion appears to be a widespread change of the mucus-secreting glands of the entire body, of which the striking findings in the pancreas are but one manifestation. The mucoproteins in duodenal fluid of most patients with cystic fibrosis have different physicochemical properties from those of normal persons. The changes in the pancreas result from obstruction by inspissated secretion which begins in the pancreatic acini and extends to the ducts. Initially there is dilatation of the acini and ducts, followed by atrophy of the acinar tissue with ultimate replacement with connective tissue, resulting in fibrosis of the entire gland. Grossly, the pancreas is usually smaller, thinner and firmer than normal. The ducts are often dilated, and at times white or yellow plugs can be seen extruding from the cross-sectioned ducts.

Microscopically, there is atrophy of the

exocrine parenchyma. The connective tissue is prominent, in part resulting from replacement fibrosis, but chiefly from condensation of the connective tissue framework of the pancreas secondary to atrophy and disappearance of acini. The acini and small and large ducts are dilated and filled with inspissated eosinophilic material. Occasionally there is an infiltration of lymphocytes and large mononuclear cells in the interstitial spaces. The islands of Langerhans are normal.

The most common early finding in the lungs is either emphysema or atelectasis, depending on whether thick, tenacious mucoid and mucopurulent secretions found in the trachea and bronchi produce complete or incomplete obstruction. Later in the disease, dilatation of bronchi and bronchioles, thickening of bronchiolar walls, bronchiolectatic abscesses and scattered areas of bronchopneumonia are seen. In long-standing cases there are pulmonary fibrosis and a chronic interstitial pneumonia. The tracheobronchial mucous glands are distended with inspissated secretion which has a microscopic appearance similar to that of the exudate observed in the pancreatic ducts and acini.

The liver is usually enlarged and infiltrated with fat. A distinctive type of *multilobular biliary cirrhosis with concretions* leading to portal hypertension occurs in about 2 per cent of cases. Apparently initiated by intrahepatic biliary obstruction from inspissated eosinophilic material (probably mucoprotein),

a trigger mechanism such as nutritional injury or infectious hepatitis is postulated to account for spreading of the localized lesions.

Distention of the acini and ducts of the salivary glands, of aberrant pancreatic tissue with inspissated secretion, and of the mucous glands of the esophagus, duodenum, jejunum and gallbladder is encountered so often as to indicate that these changes are characteristic of this generalized disease.

The sweat contains high concentrations of chloride, sodium and potassium. The saliva and tears also contain increased chloride and sodium, but normal potassium concentrations. The parotid glands tend to have an increased rate of secretion.

Chronic pulmonary heart disease, *cor pulmonale*, is evident in the right side of the heart, which shows the signs of chronic strain produced by the obstructive pulmonary disease; the right ventricle is hypertrophied, the right atrium is hypertrophied and dilated, and the walls of the pulmonary artery and the dilated pulmonary conus are thickened.

Nutritional disturbances, such as retardation of growth and wasting and disappearance of fat from the fat depots, are present in most cases. In about one quarter of Andersen's cases keratinizing metaplasia of the epithelium, characteristic of vitamin A deficiency, was found in the pancreas, upper respiratory tract, renal pelvis and salivary glands. Osteoporosis is common, but rickets is rare, probably owing to the slow rate of growth. In a

FIG. 206. Photomicrograph illustrating changes of pancreatic fibrosis. Note the generalized cystic dilatation of the acini and the interacinar fibrosis.

few cases evidences of vitamin K deficiency have been observed.

**Clinical Manifestations.** The earliest recognizable clinical disturbance is meconium ileus in the newborn infant (p. 331). Possibly because the deficiency of pancreatic enzymes is seldom complete, meconium ileus is not common. Otherwise, initial symptoms may be referable to poor intestinal digestion or infection of the respiratory tract.

Appearing normal at birth, the infant may or may not present easily detected evidence of impaired intestinal digestion. Failure of the newborn infant to regain his birth weight within the first ten days of life is suggestive. Although the stools are increased in weight and bulk from birth, this often is not noted because individual stool specimens may not appear abnormally large or loose. Almost always before the sixth month, and often before the fourth week, the abnormality of the stools becomes evident. Rarely appearing fatty, they may be loose but not frequent, or less commonly are unformed and numerous. The bulky stools of increased fat content may go unnoticed until the addition of cereal or other starch induces a foul-smelling, frothy stool. Fish liver oils given early are often detected by their odor in the fat-laden stools and at times separate out as fat droplets. After one year of age the stools are usually pale and fatty. The onset of pulmonary infection will frequently make the stools more diarrheal.

Failure to gain weight in spite of an adequate dietary intake is usually apparent early. Some infants have a ravenous appetite as a compensatory mechanism for the large fecal losses.

Manifestations of pulmonary disease are the first abnormality noted in many infants. Persistent upper respiratory and/or diffuse lower respiratory tract infections beginning within the first few weeks of life should always suggest the possibility of pancreatic fibrosis. There may be a severe spasmodic cough often followed by vomiting which is suggestive of pertussis.

Physical signs of obstruction of various parts of the bronchial tree are present at this time, and a generalized expiratory type of dyspnea and wheezing due to widespread bronchiolar obstruction is common. The severe cough results from difficulty in expelling the thick, tenacious mucus produced in the trachea and bronchi. Cyanosis and clubbing of the toes and fingers often develop, and the chest may become barrel-shaped. As a result of destructive lung disease, there is an insidious but increasing hypertrophy of the right

ventricle (cor pulmonale); the progress of the cardiac damage parallels the fluctuations in activity and severity of the pulmonary disease.

The potential length of life is undetermined; most patients die in infancy or early childhood. The longest recorded survival is about twenty-five years. Progression of pulmonary destruction is not inevitable, however; it may become stationary and infrequently has retrogressed.

In infants surviving the first six months of life the evidences of the celiac syndrome are prominent, and respiratory tract infection may at first be inconspicuous. Retardation of growth, abdominal distention, emaciation and behavior disturbances, such as occur in idiopathic celiac disease, are usually present. The stools are bulkier and more malodorous than in any other condition in childhood. Rectal prolapse is a common complication in about one fifth of patients; it is most frequent between six months and three years of age. Diabetes mellitus has been observed in a few children, becoming manifest in mid- or late childhood.

Patients with fibrocystic disease are prone to heat prostration in high environmental temperatures as a result of the abnormal losses of electrolytes in their sweat. Mothers are occasionally impressed by the "salty taste" of babies with this disorder, when kissing them.

**Diagnosis.** Demonstration of the derangements of pancreatic fibrosis by laboratory means is essential for diagnosis.

**Demonstration of deficiency of pancreatic enzymes.** The pancreatic enzymes (trypsin, lipase, amylase and carboxypeptidase) are absent or greatly reduced in the scanty, viscid duodenal fluid. For practical purposes the fluid need only be tested for the presence of trypsin; the absence of trypsin or a very low titer of it is a reliable substantiation of the diagnosis. The failure of digestion of the gelatinous coating of photographic film by application of serial dilutions of stool as spot tests is a rapid and useful screening test for the presence or absence of trypsin.\* Because other factors (bacteria) with tryptic activity may influence the test, it should not be used as a definitive diagnostic measure.

\* A piece of roentgenologic film cut to the size of a Petri dish is placed in the dish with the gelatin side up. A few drops of diluted stool (1:60, 1:120 and 1:180) prepared from a 1:6 dilution are applied to the film; water is used as a control. After incubation for one hour the film is studied for digestion of the gelatin. Dilutions of 1:120 minimize the falsely positive reactions due to bacterial gelatinase.

**Measurement of the chloride content of sweat.** The high concentration of chloride in sweat is a constant and easily demonstrable abnormality. The chloride content of sweat in normal persons does not exceed 60 mEq. per liter and usually is much less; in patients with cystic fibrosis of the pancreas it always exceeds this level. The concentrations of sodium and potassium in sweat are also elevated. The ranges of concentration of the chloride and sodium in sweat are shown in Table 91.

Shwachman has developed a screening technique in which a patient's hand is placed upon agar impregnated with silver nitrate. If the sweat chloride level is high, the hand-print is clearly seen as a precipitate of silver chloride. The test is valuable for screening patients, but it is not diagnostic.

The sweat abnormality occurs among the relatives of patients, indicating different levels of expressivity of the recessive gene in heterozygous persons.

**Deficient intestinal absorption of fat.** Increased fecal excretion of fat may be easily demonstrated by microscopic examination of diluted stool to which Sudan or scharlach stain has been added. Quantitative chemical determination of fat is more exact, but is not necessary. Poor absorption of fat may be demonstrated by the absence of free iodine in the urine after the oral administration of Lipidol. Low blood cholesterol is a constant finding and, at least in part, is secondary to the poor absorption of fats.

Poor absorption of vitamin A (p. 720) is another evidence of failure of fat digestion. Absorption curves with oily vitamin A preparations are flat, but with the alcoholic form of vitamin A they are normal, in contrast to the results in idiopathic celiac disease, in which both forms of vitamin A are poorly absorbed.

**Roentgenologic studies.** Roentgenograms of the intestinal tract reveal changes similar to those seen in idiopathic celiac disease: viz.,

clumping of the barium with alternate segments showing dilatation and spasm resulting in loss of the normal mucosal pattern. These findings, however, are not diagnostic. The earliest pulmonary changes are those of generalized obstructive emphysema with little evidence of infiltration later; patchy areas of atelectasis are evident. With the development of severe bronchial disease an increase in the density and extent of the hilar shadows, patchy areas of bronchopneumonia, bronchiectasis and bronchiolectatic abscesses can be visualized.

Right ventricular hypertrophy and prominence of the pulmonary conus are demonstrated in well advanced cases of pulmonary disease with cor pulmonale.

**Blood.** Other than the changes occurring with infection, there are no significant alterations in the red or white blood cells.

**Treatment.** Maintenance of good nutrition, the control of pulmonary infection and the prevention and/or restoration of abnormal losses of salt are the main objectives of treatment.

To compensate for the stool losses of nutrients, an unrestricted intake of a balanced diet providing 6 to 8 gm. of protein per kilogram of body weight and usual amounts of fat is preferable if it can be clinically tolerated. Dietary fat is usually reduced initially to control the bulk and character of the stools. Pancreatic extract (1 gm. of a patent pancreatin, such as Viokase, per 6 to 8 ounces of formula, or 2 to 3 gm. before each meal) is also helpful in improving the stools. Foods should be salted liberally, and in hot weather an additional 2 gm. should be provided daily.

For infants the dietary specifications may be fulfilled initially by a protein milk formula fortified with added skimmed milk powder and with banana powder, sucrose, glucose or honey. Vitamins in a water-miscible preparation should be given in amounts about three times those usually recommended. The caloric intake should range from 150 to 200

Table 91. Sweat Electrolyte Concentrations in Normal Persons and in Patients with Cystic Fibrosis of the Pancreas

calories per kilogram of body weight per day, if possible. By about three months of age, solid foods are added to the diet.

Some patients with pancreatic fibrosis have remained free from pulmonary infection on dietary management alone. Isolation during infancy and good hygienic surroundings for all children are important in the prevention of respiratory tract infection. Hospitalization, because of its hazard as a source of infection, should be as brief as possible. Prophylactic administration of antibiotics is indicated as soon as a diagnosis of pancreatic fibrosis has been made and, when combined with dietary therapy before pulmonary involvement has set in, offers the greatest hope of delaying the onset of respiratory infection and of prolonging life. The necessity for early diagnosis is obvious. Since the basic infection is usually due to staphylococci, penicillin is administered by inhalation (100,000 units five times daily) and by intramuscular injection (800,000 units daily), and one of the tetracyclines, chloramphenicol or erythromycin combined with sulfisoxazole (Gantrisin) is given orally. If gram-negative bacteria are present in the nasopharyngeal cultures, streptomycin is added to the inhalations (200 mg. five times daily) and to the intramuscular injections (30 mg. per kilogram per day in two divided doses). This antibiotic treatment is continued for seven to fifteen days, after which prophylactic therapy with one of the broad-spectrum antibiotics is continued as long as any signs of pulmonary infection are present. Antimicrobial therapy is best selected on the basis of dilution sensitivity tests *in vitro*. There is suggestive evidence that tetracycline may have beneficial effects on the nutrition, independent of its prophylactic antibacterial actions.

Information about the eugenic implications should be available to parents of a child with pancreatic fibrosis. The possibility that a child with this disease may reach adulthood leads to some interesting eugenic speculations.

### PANCREATIC DYSPLASIAS SIMULATING CYSTIC FIBROSIS OF THE PANCREAS

Several rare conditions are recognized in which congenital defects in the pancreas or its ducts obstruct the flow of pancreatic juice to the intestinal lumen. Such conditions which produce digestive failure resembling that of pancreatic fibrosis include (1) congenital obstruction of the main pancreatic ducts of Wirsung and Santorini; (2) con-

genital hypoplasia of the exocrine pancreas. In this rare embryologic maldevelopment the terminal pancreatic ducts fail to unite with the acini and larger ducts, so that the acini are replaced by fat. The ducts are not occluded or distended as in pancreatic fibrosis. (3) Congenital cystosis of the pancreas; this is a congenital malformation of the duct system in which isolated segments of duct form true epithelial cysts surrounded by normal pancreatic tissue.

It is noteworthy that bronchial abnormalities and infection and disordered formation of mucus by other glandular structures which occur with fibrosis of the pancreas are not associated with these other conditions, even though they completely exclude pancreatic juice from the intestine.

### ACUTE PANCREATITIS

#### MUMPS PANCREATITIS

Acute nonsuppurative pancreatitis occurs as a rather infrequent complication of mumps. It usually makes its appearance abruptly three to four days after the first sign of salivary gland involvement, but it may occur somewhat later. During epidemics of mumps some children have had symptoms typical of acute pancreatitis without involvement of the salivary glands. The onset of the disease is abrupt, with severe, constant abdominal pain localized most frequently about the umbilicus, but at times in the epigastrium. Shock, nausea, and vomiting are almost always present. Diarrhea is a frequent occurrence, but in rare instances the passage of large, fatty stools is recorded. Moderate fever is often present, and leukocytosis is a fairly constant finding. Polyuria and urinary frequency may occur. Transient hyperglycemia and glycosuria are noted infrequently either during or after the acute attack. Tenderness may be elicited in the upper abdomen in the region of the pancreas. The *prognosis* is usually good, complete recovery occurring in about one week. In a few instances suppuration of the pancreas has developed.

#### HEMORRHAGIC, SUPPURATIVE AND GANGRENOUS PANCREATITIS

Acute pancreatitis of this category, not uncommon in adults, in whom it is readily recognized clinically and is frequently associated with biliary tract disease and precipitated by overeating, is rare in childhood. When detected, it is usually an accidental finding at

an abdominal operation or at autopsy. Of thirty-eight cases up to 1958, twenty-four were of unknown etiology. Some cases have been secondary to trauma, and the signs of pancreatitis may be overshadowed by those of concomitant injury of the spleen or liver. Obstruction of the pancreatic ducts by *Ascaris* has initiated the disease in a few instances. Occasionally, septic emboli or extension of a neighboring infection (peritonitis or retroperitoneal abscess) is responsible. Rarely, hemorrhage into the pancreas from purpura or leukemia is the cause. Prolonged administration of corticosteroids may cause acute pancreatitis. It is postulated that alteration of pancreatic secretion leading to obstruction and release of pancreatic enzymes is responsible for the lesions. Irrespective of the etiologic agent, the evolution of the disease follows the same pattern. The zymogens, trypsinogen and steapsinogen, which have no enzyme activity in the pancreas or its ducts, are activated by a substance released from autolyzed injured pancreatic tissue. The activated enzymes, trypsin and steapsin, then produce autodigestion of the protein and fat of the pancreas and surrounding tissues. Absorption from the necrotic pancreas undergoing autolysis is responsible for the fulminating toxemia. Tetany due to binding of calcium by fatty acids may occur. Diabetes mellitus may develop during or after an attack, as a result of destruction of islet tissue. Pseudocyst formation is a relatively common complication.

The onset of the disease is sudden and is characterized by agonizing, constant upper abdominal pain, nausea, vomiting and symptoms of shock. If the nature of the disease is suspected, confirmation may be made by the finding of an increase in serum or urinary diastase. Treatment consists of parenterally administered glucose fluids and antibiotics to prevent secondary bacterial infections. Sympathicomimetic drugs (methantheline bromide) are used to reduce pancreatic secretion. Surgery is necessary if a pseudocyst, hemorrhage or abscess occurs as a complication.

#### INVOLVEMENT OF THE PANCREAS IN SYSTEMIC DISEASE

Acute and chronic changes in the pancreas are often associated with a variety of systemic diseases without producing symptoms that would lead to clinical recognition of pancreatic involvement. Infiltration of the pan-

creas by leukemia, Hodgkin's disease and other lymphogranulomatous conditions is common. Severe congenital syphilis involving the pancreas causes widespread fibrosis. Fibrotic changes with extensive atrophy of acinar tissue result from the chronic passive congestion of the pancreas produced by long-standing cardiac decompensation. Miliary abscesses occur in association with septicemia; tubercles, with miliary tuberculosis.

#### NEOPLASMS AND CYSTS OF THE PANCREAS

Tumors of the pancreas are exceedingly uncommon in infancy and childhood. Primary sarcoma and carcinoma are recorded, but their extreme rarity is indicated by Dargeon's tabulation in 1538 cases of malignant tumors in childhood, of which only three were in the pancreas. Metastases from melanosarcoma, hemangiosarcoma and lymphosarcoma may involve the pancreas, but carcinoma in childhood rarely metastasizes to this organ. Adenoma of the islets of Langerhans is discussed on page 1217.

A variety of pancreatic cysts is encountered in children. Post-traumatic *pseudocysts*, not infrequently sequels of bicycling accidents, are of especial interest because they grow rapidly to large size and cause pressure damage which may be irreversible. Vomiting and weight loss are common symptoms, and a large soft mass usually occupies the left upper abdominal quadrant. Roentgenograms taken after barium ingestion may show elevation of the left diaphragm and upward displacement of the stomach. Prevention of the serious pressure effects of pseudocysts by early surgical intervention depends upon an awareness of the possible development of the lesion after severe trauma to the pancreatic area.

Occasionally pancreatic cysts are congenital and associated with polycystic disease elsewhere. Retention cysts, lined with epithelium due to obstruction, may follow chronic pancreatitis. Extremely rare are neoplastic cysts (cystadenoma, cystadenocarcinoma or teratoma). Echinococcus cysts of the pancreas are encountered in areas where this parasitic disorder occurs.

# The Respiratory System

## RESPIRATORY PHYSIOLOGY AND ITS APPLICATION TO PULMONARY DISEASE

A fundamental knowledge of respiration is essential for a proper understanding of respiratory disease. This section will deal with basic principles, some measurements of pulmonary function, and the application of such knowledge to certain respiratory conditions in infants and children. The respiratory system is made up of (1) a control system, which consists of a respiratory center in the brain stem, chemoreceptors in the carotid and aortic bodies, and peripheral nerves which are both motor (efferent) and sensory (afferent); (2) the respiratory muscles and "thorax"; (3) the lungs and the pulmonary vasculature. Any one or combination of the parts may be involved in disease processes which may contribute to pulmonary disability.

### CONTROL OF RESPIRATION

The respiratory center in the brain stem has an inherent rhythmicity which is modified by proprioceptive afferent impulses from the lungs, by various reflexes and voluntary mechanisms, and by changes in the oxygen and carbon dioxide tensions in the arterial blood. The proprioceptive impulses from the lungs are carried by the vagi; the complete cycle from proprioception to the motor response is called the *Hering-Breuer reflex*. Protective reflexes such as coughing and sneezing can alter the usual breathing patterns and act to eliminate foreign or obstructing matter from the respiratory system. Respiration is also modified during swallowing and is altered reflexly by pain, fever, and variations of blood pressure.

Oxygen lack stimulates the respiratory center principally through the carotid and aortic

\* "Thorax" in this presentation is used to include the diaphragm, rib cage, abdominal wall and abdominal contents.

body mechanisms, whereas changes in carbon dioxide tension affect the respiratory center directly. Whether carbon dioxide tension or the associated change in pH (in blood or cerebrospinal fluid) is more responsible for regulation of the respiratory center is not known, but it is recognized that respiration is very sensitive to *small* changes in the carbon dioxide tension of the blood whether secondary to respiratory or metabolic abnormalities. Both *pronounced* hypoxia and hypercapnia have a depressant effect on the respiratory center, and this is an important consideration in the management of apnea, resuscitation or chronic respiratory insufficiency. Furthermore, anesthetic agents and certain drugs such as opiates and barbiturates, hypothermia and brain injury also depress the respiratory center. The best stimulus to a depressed respiratory center is an increase in its supply of oxygen. Drugs are useful as respiratory center stimulants only as they improve the general circulation or specifically counteract a respiratory, depressant (e.g., n-allylnormorphine).

### MUSCLES OF RESPIRATION

In quiet normal breathing only the inspiratory muscles are used; expiration occurs as a result of relaxation of the respiratory muscles and the elastic recoil of the lung. The diaphragm is the most important muscle of quiet inspiration, but with increasing inspiratory effort the intercostal, spinal extensor and neck muscles become active in that order. They tend to increase the thoracic diameter and thus the volume of inspiration; the intercostal muscles also serve to stabilize the rib cage.

The abdominal muscles are the ones primarily used for a forced expiration; they are assisted by the "spinal flexors," which increase

intrapulmonary pressure for coughing. The intercostal muscles also assist expiration, but here, too, they function largely to stabilize the rib cage. Patients with weakened abdominal muscles cannot cough well. Manual pressure over the abdomen after a maximal inspiration can produce a fair cough when the closed glottis is opened suddenly, but this technique is limited to patients who can cooperate.

When muscular function is diminished as with poliomyelitis or other neuromuscular disease, the forces developed may be so limited that artificial respiration is required.

## PULMONARY SUBDIVISIONS

Some of the functional subdivisions of lung volume are shown in Figure 207, A, which represents a series of tidal volumes and a vital capacity as obtained on a recording spirometer. Predicted normal values for vital capacity can be obtained from the following relationships:

	5-15 Years	16+ Years
Males.....	250 cc./yr. age	25 cc./cm. Ht.
Females.....	200 cc./yr. age	20 cc./cm. Ht.

These estimations are clinically useful, but not sufficiently accurate for research purposes. The limits of normal values for various ages are given in Table 92.

The vital capacity is made up of the inspiratory capacity and the expiratory reserve volume. The proportion of the vital capacity occupied by each of these subdivisions varies with position of the patient, although vital capacity itself changes little.

After each expiration a considerable volume of air, the functional residual capacity, remains in the lungs. It acts as a buffer to minimize changes in the partial pressure of carbon dioxide and oxygen in the alveoli and arterial blood with each breath, and tends to reduce the surface forces, since most air spaces remain open at end-expiration.

The functional residual capacity varies with changes in position, being larger in the upright than in the horizontal or recumbent position. If a person lies on his side, the lower or dependent lung has a smaller functional residual capacity than the upper lung. The volume of the functional residual capacity (the resting end-expiratory volume) is determined by the balance between the elastic recoil of the lungs and the tendency of the "thorax" to expand. The effective "thoracic" forces stem from the elastic characteristics of the rib cage, from the diaphragm and the abdominal wall, and from the hydrostatic forces of the abdominal contents. The movement of the abdominal contents is largely responsible for the changes in the functional residual capacity which occur with changes in position, and it is this movement which makes possible the use of tilting methods for artificial respiration. The functional residual capacity may be measured by means of gas dilution techniques, the simplest and easiest of which is to use helium in a closed circuit.

## MECHANICS OF RESPIRATION

The mechanical properties of the respiratory system may be divided into two components—one concerned with static or elastic forces

and the other concerned with the dynamic or flow-resistance forces. The resting end-expiratory position or functional residual capacity results from two forces—the tendency of the lungs to collapse and the tendency of the “thorax” to expand. This can be likened to the balance between two springs. Any deviation from the balance point requires work or an applied force; when the force is released, the springs return to their relaxation or balance point. In a comparable manner in normal breathing when the respiratory muscles contract, the “thorax” and lungs expand. When the muscles relax, the intrapleural pressure falls toward the resting end-expiratory pressure, and expiration occurs.

The elastic or “springlike” characteristic is called *compliance* and is expressed as milliliters or liters per centimeter of water. In the case of the lungs it represents the change in pulmonary volume for a unit change of intrapleural pressure and must be measured when there is no flow of air so that there is no flow-resistance component. The less the volume change produced by a given pressure change, the stiffer or more uncompliant are the lungs. Conversely, if the volume change for this same pressure difference is large, the lungs are said to be highly compliant or distensible.

The lungs of infants are less compliant than those of older children and adults (Table 92), but when the difference in lung size or body size is considered, they are comparable, and at all ages nearly the same transpulmonary pressure difference is required to produce the resting tidal volume. In order to measure the compliance of the lungs, one should know the intrapleural pressure

changes, but this approach has limited use. Pressure changes in the thoracic esophagus, however, may be used as an index of the transpulmonary pressure changes.

The pressure-volume relationship of the lungs and “thorax” can be related to the pulmonary compartments, as has been done in Figure 207, B. The resting end-expiratory volume has been continued as a horizontal line and also represents the pressure axis. Volume is represented by the vertical axis. Pressure changes to the right of the vertical axis are equivalent to positive airway or negative tank pressure, and pressures to the left represent negative airway or positive tank pressure. The pressure-volume relationships of the lungs and “thorax” over the vital capacity range are represented by the solid curve. There is no scale, because the values for subjects of different sizes are different; the shape of the curves, however, will be similar. In the region of the tidal volume (between A and B on the curve) the relationship of pressure to volume is essentially linear. With spontaneous respiration the strength of the respiratory muscles is an important factor in determining the magnitude of maximum volume change. In addition maximum inspiration is limited by the decreased compliance of the lungs, the rib cage, and the abdominal wall and abdominal contents at large lung volumes. Expiration, on the other hand, is limited by the compliance of the rib cage and the diaphragm.

Knowledge of pressure-volume relationship of the lungs and “thorax” is particularly important during artificial respiration. Pressures required to produce volume changes of the lungs and “thorax” are approximately twice those required for the lungs' alone.

Thus far the force required to maintain the lungs under static conditions has been considered. During inflation and deflation dynamic factors are also present. These are the resistance of the airway to the flow of gases and the viscous resistance of the pulmonary tissues. They are combined in the measurement of pulmonary flow resistance, which is the force or pressure difference required to produce a specific flow of air and is expressed as milliliters of water per liter per second (Table 92). In diseases such as asthma or bronchiolitis the pulmonary resistance may be increased to ten to fifteen times the normal value (Table 93). Since resistance to the flow of air through tubes is inversely related to the radius of the tube to the fourth power, inflammation or mucus (e.g., croup, bronchiolitis) is most likely to produce serious obstruction and increases in flow resistance in small infants and children.

A convenient method for indirect estimation of resistance is the rapidly expelled (timed) vital capacity. This requires the patient's cooperation, but is useful as a screening test or to assess effectiveness of therapy. Normally the patient should be able to expel at least 75 per cent of his vital capacity in the first second and 90 per cent within two seconds. If he has increased flow resistance, the percentage of vital capacity expelled in the allotted time will be decreased. The maximum breathing capacity or the greatest amount of air that can be rhythmically breathed out in a fifteen- or twenty-second period can also be used, but it requires more cooperation on the part of the patient. Furthermore, the extensive respiratory effort may be contraindicated in certain diseases such as active tuberculosis.

The respiratory muscles must have suffi-

cient work capacity to overcome the elastic and flow resistance of the respiratory system. During normal resting respiration the amount of work is small, corresponding to 1 per cent of the resting metabolism. As ventilation is increased the expenditure of energy for breathing increases more rapidly than the ventilation. Normally, except at extreme work loads, the respiratory system is able to meet the metabolic needs for oxygen consumption and carbon dioxide excretion. On the other hand, in disease resulting in stiff lungs or in an increased resistance to air flow the work required may be greatly increased. In such instances if there are also interference with transfer of gas from the alveoli to the blood, poor distribution of gas within the lungs and increased metabolic needs as with fever and anxiety, exhaustion of the respiratory muscles may result, accompanied by accumulation of carbon dioxide and eventually death.

Since the respiratory system is usually regulated to accomplish ventilation with a minimum expenditure of energy, there is a balance between the efficiency of the muscular activity and the effectiveness of the ventilation. In some diseases with stiff lungs, such as pulmonary fibrosis and the hyaline membrane syndrome (Table 93), the breathing is usually rapid and shallow in order to minimize the elastic work, but much dead space ventilation results. In asthma the breathing tends to be deep and slow, and the lower flow rates reduce the work required to overcome flow resistance.

VENTILATION

The volume of gas breathed into or out of the lungs with each breath is defined as the tidal volume (V<sub>T</sub>). This volume multiplied

by the respiratory rate ( $f$ ) gives the minute volume ( $\dot{V}_E$ ). Not all the tidal volume is effective in gas exchange; in the normal person about one third of each quiet respiration ventilates the dead space ( $V_D$ ), while the remaining portion ( $V_{Te}$ ) enters the air sacs and alveoli and participates in gas exchange. Since alveolar ventilation ( $\dot{V}_A$ ) is a function of carbon dioxide production ( $\dot{V}_{CO_2}$ ) and the partial pressure of carbon dioxide in the arterial blood ( $P_{aCO_2}$ ) or alveoli, the following expressions are useful for defining the effective or alveolar ventilation:

$$V_T - V_D = V_{Te}$$

$$V_{Te} \times f = \dot{V}_A = k \frac{\dot{V}_{CO_2}}{P_{aCO_2}}$$

Thus, as metabolism and carbon dioxide production increase, the alveolar ventilation must increase if the blood carbon dioxide partial pressure is to remain at the usual level. Conversely, if  $\dot{V}_A$  were doubled for a given  $\dot{V}_{CO_2}$ , then  $P_{aCO_2}$  would be halved. It is also apparent that when the dead space increases, secondary to disease or to the use of an anesthetic apparatus,  $V_T$  or  $f$  must increase to maintain a constant  $P_{aCO_2}$ .

The most effective way to increase alveolar ventilation is to increase the tidal volume. In this way alveolar ventilation is increased without increasing the dead space ventilation. This concept is presented in Table 94, in which tidal volume and frequency of breathing are varied while the minute volume is kept constant. Under such conditions, as the tidal volume decreases, the frequency increases and the amount of effective or alveolar ventilation decreases. As a result the alveolar  $P_{CO_2}$  would rise from a normal value of 40 mm. of mercury at the largest tidal volume to 60 mm. at the smallest tidal volume. The alveolar  $P_{CO_2}$  and arterial  $P_{CO_2}$  are considered to be essentially identical. If, on the other hand, the tidal volume increases

from a normal value of 0.125 to 0.5 liter, then alveolar ventilation increases and alveolar  $P_{CO_2}$  falls from its normal value of 40 mm. to about 27 mm. of mercury.

**Methods of Measuring Ventilation.** The adequacy of ventilation is best evaluated by measurement of alveolar or arterial partial pressure of carbon dioxide. The measurement of "alveolar" or end-tidal  $P_{CO_2}$ \* is the more practical and can be nearly continuous or at least repeated frequently. Since it provides an approximation of the arterial  $P_{CO_2}$ , it is a good index of the effectiveness of the ventilation. It is relatively easy to obtain with an infra-red carbon dioxide analyzer, but the equipment is expensive and not easily adapted for infants and small children.

The adequacy of ventilation can also be estimated by measuring the minute volume ( $\dot{V}_E$ ), by means of a recording spirometer or a ventilation meter (Fig. 209). The measured tidal volumes are then compared with the predicted values obtained from a nomogram (Fig. 208) at the observed frequency of breathing. The nomogram is based on assumptions that the arterial  $P_{CO_2}$  at sea level should be close to 40 mm. of mercury and that the lungs are relatively normal and that body weight is a good index of the person's metabolism or carbon dioxide production. Knowing the weight and the frequency of breathing, one can then predict the required tidal volume. This calculation is most applicable for regulating artificial respiration in poliomyelitis or during anesthesia. Use of the nomogram is demonstrated in the following example:

A 40-pound male child requires artificial ventilation; his temperature is 40° C., he is breathing through a tracheostomy tube, he is not in coma, and he is at an altitude of 3000 feet. Respiratory frequency is set at 20 per minute. Corrections to be

\* End-tidal  $P_{CO_2}$  is not necessarily true alveolar  $P_{CO_2}$ , but is a useful approximation.

0.125.....	5	40	2.0	3.0

FIG. 208. Nomogram for regulation of artificial respiration.

Corrections to be applied to basal tidal volume:

For Metric System:

1. Add 10 per cent for daily activity (i.e., patient not in coma).
2. Add 9 per cent for each  $1^{\circ}$  C. above  $37^{\circ}$  C. rectal temperature.
3. Add 8 per cent for each 1000 M. altitude above sea level.
4. Subtract 1 cc./kg. weight if patient is breathing through a tracheostomy or endotracheal tube.

For English systems:

1. Add 10 per cent for daily activity (i.e., patient not in coma).
2. Add 5 per cent for each  $1^{\circ}$  F. above  $99^{\circ}$  F. rectal temperature.
3. Add 5 per cent for each 2000 ft. above sea level.
4. Subtract volume (cc.) equal to one-half body weight expressed as pounds if patient is breathing through a tracheostomy or endotracheal tube.

FIG. 209. Measuring ventilation on small child by means of mask and meter.

applied to basal tidal volume are listed on the nomogram and demonstrated below.

Basal tidal.....	135 ml.	
Awake +10%.....	14 ml.	
Fever +3 × 9 = 27.....	36 ml.	
Altitude +1.5 × 5 = 7.5%...	10 ml.	
	195 ml.	
Tracheostomy -40/2.....	-20 ml.	
	175 ml.	predicted required V <sub>T</sub> via tracheostomy tube

Predicted required minute volume is  $V_T$  times  $f$ ; i.e.,  $\dot{V}_E$  is 175 times 20, or 3500 ml. per minute.

Cyanosis is, of course, an indication of respiratory insufficiency except in patients with shock, cardiovascular disease or methemoglobinemia. If cyanosis occurs in spite of adequate ventilation as judged either by measurement of minute volume or, better still, by end-tidal  $P_{CO_2}$  measurements, then the need is for more oxygen, and not for an increase in ventilation. An increase in ventilation under such circumstances produces relatively little change in arterial oxygen saturation, but removes significant amounts of carbon dioxide from the body, lowers the  $P_{CO_2}$  and increases the pH until compensation occurs. A decreased  $P_{CO_2}$  even in the presence of a compensated pH is not a normal state and may cause personality changes in the patient.

## PARTIAL PRESSURES OF GASES

The partial pressures of gases at sea level in various physiologic media of the normal person are presented in the bar graphs in Figure 210. These are not valid at altitudes much above sea level, since the lower barometric pressure reduces the partial pressure for all gases except that of water vapor. The latter is related to the temperature of the air and remains fixed at 47 mm. of mercury at 37° C. If the patient is febrile, the vapor tension increases; an elevation of 2 to 3° C. adds about 10 mm. of mercury to the partial pressure of water vapor. The water vapor then occupies more space and displaces other gases.

Owing to the differences in the  $P_{O_2}$  of alveolar gas and arterial blood, the sum of the partial pressures in the arterial blood does not add up to the ambient barometric pressure. In normal persons most of this difference is due to a small venous admixture or "shunt" into the arterial system and very little to a

diffusion gradient from the alveoli to the red blood cell. When there are abnormal ventilation (alveolar)-perfusion (blood flow) relationships, "shunted blood" may be considerable. Thus if a part of the lung is underventilated in relation to its perfusion, the blood exposed to these underventilated alveoli may approximate venous blood, and in effect this blood is shunted. If an area is overventilated and receives relatively little blood, the result is the same as an increase in the dead space. Even if perfused alveoli are hyperventilated, the blood is not able to take up much more oxygen and cannot compensate for blood that is unsaturated. The explanation lies in the shape of the oxyhemoglobin dissociation curve, which is sigmoid and flattens out near 100 mm. of mercury. When the arterial  $P_{O_2}$  is about 95 mm. of mercury, the hemoglobin is about 97 per cent saturated, and a further increase in the  $P_{O_2}$  by hyperventilation adds little oxygen to the blood. On the other hand, the mixture of 5 per cent venous blood to arterialized blood produces a significant fall in the oxygen tension because such unsaturated blood is on the steep part of the dissociation curve where considerable amounts of oxygen can be taken up for small changes in partial pressure.

The sum of the partial pressures in the mixed venous blood is much less than in the

FIG. 210. Partial pressures of gases in various physiologic media at sea level (Barometric pressure, 760 mm. Hg.).

arterial blood. Again this is largely due to the decrease in venous  $\text{Po}_2$ . There is only a small increase in the venous  $\text{PCO}_2$  because the blood can carry large amounts of carbon dioxide with little change in partial pressure of carbon dioxide. The difference between the alveolar  $\text{Po}_2$  and the venous  $\text{Po}_2$  is large (40 to 60 mm. of mercury) and acts as the initial driving force to deliver oxygen from the alveoli into the blood.

Measurements of the diffusing capacity of the lungs can be made by using carbon monoxide as the indicator gas. In infants and small children they are technically difficult, and particularly so in disease states.

## INITIATION OF RESPIRATION

The onset of respiration is the most critical adjustment required of the infant. Thus it is not surprising that most neonatal deaths are related to failure of respiration. Although before birth the lungs have no obvious function, there is ample evidence that there are rhythmic respiratory-like movements of the fetus in utero. The resultant movement of amniotic fluid into the lungs may facilitate their expansion at birth.

Extrapolations to the human fetus from the experimental observations of Barcroft in fetal lambs suggest that the onset of respiration is usually produced by sensory stimuli (tactile or thermal). When central nervous system depression exists, chemical changes may act as an emergency mechanism to stimulate the respiratory center. But the apneic infant is already hypoxic and acidotic, and the administration of carbon dioxide may only lead to further depression.

With the first breath certain forces must be overcome to expand the lungs and permit adequate ventilation. Under normal circumstances the greatest force opposing expansion of the fetal lung is surface tension, but, in addition, there is their elastic recoil as well as flow resistance. Measurements by Karlberg of the first few respirations have demonstrated that the transpulmonary pressures required to expand the normal lung may be 20 to 50 cm. of water. Although these high pressures normally are produced by the infant himself, alveolar rupture may occur either spontaneously or as a result of artificial respiration. Thus positive pressure, when indicated, must be used with caution.

The respiratory mechanism at birth is most likely to fail as the result of (1) central

nervous system depression or (2) abnormalities within the lungs. Drugs, intrauterine hypoxia and trauma may all depress the respiratory center. Unless morphine antagonists are indicated, little can be done to improve the responsiveness of the center except to supply it with oxygen and to remove excess carbon dioxide. Good obstetric and anesthetic procedures should greatly reduce the incidence of this type of respiratory failure.

Expansion of the lungs may be limited because of obstruction which can be removed if it is in the larger air passages. If the obstruction is in the smaller air passages, as may occur with aspiration of meconium-containing amniotic fluid or with plugging of alveolar ducts with hyaline-membrane material, the lungs may be resistant to expansion. The latter type of respiratory distress is the greatest single cause of death in the newborn period.

Congenital malformations such as diaphragmatic hernias, lung cysts, intrathoracic tumors and tracheo-esophageal fistulas may also be a cause of respiratory difficulty in the newborn period and may at times simulate conditions which have less specific therapy.

## ARTIFICIAL RESPIRATION

Although obvious technical and quantitative differences exist, the basic principles of artificial respiration are the same for all ages. These are as follows:

1. Maintenance of an adequate airway by:
  - a. Prone position for drainage
  - b. Extension of neck with forward traction on mandible
  - c. Gentle suction
  - d. Intubation or tracheotomy
2. Institution of adequate ventilation as quickly as possible
3. Avoidance of injury to the patient

Severe hypoxia of only a few minutes may lead to irreversible damage, especially to the brain. Fortunately the newborn infant can tolerate hypoxia better than older persons, but, since the duration and severity of intrauterine hypoxia are impossible to gauge accurately, one should not delay resuscitative procedures even in the newborn. Oxygen administration is a useful adjunct, but is no substitute for adequate ventilation.

The methods of producing artificial respiration are (1) manual methods, (2) positive pressure applied to the airway, or negative pressure about the body, (3) rhythmic rock-

ing of the patient, (4) electrical stimulation of the phrenic nerve.

**Newborn Infant.** The normal newborn infant should not require resuscitation. If respiration has not started by thirty to sixty seconds after birth and is not fully established by one to three minutes, the central nervous system is probably depressed. Initially a free airway should be established. For this purpose an oral airway is usually adequate, although under special circumstances, and when an experienced person is available, tracheal intubation may be useful. When intubation is used by unskilled persons, however, more harm than good may be done.

If not expanded, the lungs may most practically be inflated by positive pressure applied by a mask or through the endotracheal tube. The magnitude of the pressure necessary and its duration are variable for each infant. Available data suggest that transpulmonary pressures up to 20 cm. of water are usually safe, but in many instances pressures of 30 to 50 cm. may be necessary for adequate expansion. If such pressures are necessary for expansion of the lungs, even higher pressures will obviously be required for expansion of both the lungs and the chest. Certainly high pressures, if used at all, should be used with caution and for brief periods only (probably for less than 0.5 second). Furthermore, high pressures should be applied only to infants with unexpanded or incompletely expanded lungs.

Pressures may be applied and controlled by a variety of machines and with practice and experience by mouth-to-mouth or mouth-to-tube resuscitation. The latter techniques have the disadvantage that there is a chance of cross infection between the patient and the physician, and pressure is difficult to gauge or control. Since hypoxia causes depression of the respiratory center itself, supplemental oxygen should be supplied in all instances until spontaneous respiration is established. In the newborn particularly, but in anyone subjected to artificial respiration, the effectiveness of the procedure should be checked not only by observation of the excursion of chest and abdomen and auscultation of the lungs, but also, when possible, by measurements of the ventilation.

For the infant whose lungs have never expanded, rocking will accomplish little; subsequently the effectiveness of rocking is in direct proportion to the size of the infant. Hence rocking is of little direct use in small infants as a ventilating maneuver. Central

nervous system stimulants (other than oxygen) are of little or no use and in some instances may be harmful. Tubbing, spanking, jackknifing and manual compression of the thorax are all dangerous and ineffective. Phrenic nerve stimulation produces a more natural type of breathing, but has limited practical use because of the need for special equipment and a trained operator.

**Infants and Older Children.** Since the lungs of older infants and children have already been expanded, other techniques are applicable. Positive pressure (e.g., mouth-to-mouth) is useful once a free airway has been established. In addition, manual compression and expansion of the thorax as in the back pressure-arm lift method or back pressure-hip lift method can produce an adequate ventilation provided there is no respiratory obstruction. Electrical stimulation of the phrenic nerve is more practical than it is in the newborn infant. For more prolonged artificial ventilation the tank type of respirator, endotracheal positive pressure, the rocking bed and special chest-type or cuirass respirators can be used. The cuirass respirators have limited usefulness in infants and small children because the chest is compressed and ventilation may be insufficient. When mechanical artificial ventilation is required for a prolonged period, the patient should be given deep breaths at regular intervals in order to minimize the development of atelectasis.

The effectiveness of various types of ven-

FIG. 211. Effectiveness of breathing machines.

tilating devices is presented in Figure 211. The endotracheal positive pressure technique produces the greatest tidal volume, owing to the compression of the gas within the lungs. The effectiveness of the cuirass respirators varies with the amount of the body that is enclosed within them and the freedom of motion allowed. The rocking beds are not included since there is great variation with the size of the patient.

There is no special pressure that should be used for different age groups. The pressure or degree of tilting should be set so that the required tidal volume or an end-tidal  $P_{CO_2}$  of 40 mm. of mercury is obtained. This requires measuring the tidal volume and comparing it with the predicted values from the nomogram (Fig. 208) or measuring the end-tidal  $P_{CO_2}$ . If the device is unable to produce sufficient pressure at a given frequency, adequate ventilation may be obtained by increasing the frequency, which in turn usually increases the pressure developed. A new calculation from the nomogram will be necessary, since the predicted tidal volume will be different.

## INHALATION THERAPY

Besides oxygen, the most frequently used agents for inhalation therapy are water, antibiotics and bronchodilators, which are administered in compressed air or oxygen.

**Oxygen Therapy.** The therapeutic use of oxygen is not without danger. Inhalation of oxygen in concentrations greater than 60 per cent for a period of days is toxic in animals and human beings. In premature infants concentrations of oxygen over 30 per cent increase the incidence of retrolental fibroplasia. These potential dangers do not, however, preclude the use of oxygen for infants with respiratory distress when it is specifically indicated to prevent severe hypoxia.

A less well appreciated effect of oxygen therapy occurs when patients suffering from chronic underventilation are given oxygen to combat cyanosis. These patients may stop breathing and die because the drive to breathe, which came from the low blood oxygen tension, is removed. Owing to chronic underventilation, blood carbon dioxide tension may be high and the respiratory center no longer responsive to carbon dioxide. If the carbon dioxide is high initially ( $P_{aCO_2}$ ), about 80 mm. of mercury, a further increase may reach narcotic levels, and the patient will become comatose. In such a situation artificial respiration may be necessary.

**Water.** The administration of air or oxygen supersaturated with water has long been used when there is evidence of increased or tenacious secretions and narrowing of the larger air passages (as with laryngitis or tracheobronchitis). Similarly, inhalation of water vapor is important in the management of patients breathing through a tracheostomy tube, when the normal humidifying action of the upper respiratory system is bypassed.

The use of vaporized water in peripheral pulmonary disease is less certainly effective. The air from the lower part of the trachea to the periphery of the lung is normally saturated with water at body temperature, whereas air saturated with water at room temperature (24° C.) is only 50 per cent saturated when raised to body temperature. Thus a saturated atmosphere does not necessarily supply saturated gas to the peripheral air passages. The effect, if any, of water vapor on peripheral pulmonary disease of all age groups needs further critical study. When used, water vapor is best administered as a cool mist.

**Antibiotics.** Inhalation of antibiotics in compressed air or oxygen (aerosols) is occasionally useful in the control of severe, diffuse pulmonary disease, (e.g., cystic fibrosis of the pancreas). In most instances, however, the same agents may be as effective and more easily administered orally or parenterally. Furthermore, the distribution of ventilation, as well as the droplet size, the growth of the droplets, the polarization of the particles, and possibly other factors determine the penetration of an aerosol into the smaller pulmonary units and thus impose limitations on aerosol therapy.

**Bronchodilators.** A number of bronchodilators can be effectively administered by inhalation. This route has the physical advantage that it is easy for the patient and the psychologic advantage that it is a means of treating directly the bronchoconstriction and thus the patient's symptoms. The disadvantage of this route is the difficulty in controlling dosage.

## AGE AS A FACTOR IN RESPIRATORY DISTURBANCES

Respiratory disturbances constitute one of the major problems of pediatric practice. Some of these disorders are confined to the very young infant, and others occur most frequently in that age group. Furthermore, the clinical patterns of most respiratory diseases are influenced by the patient's age.

**Newborn Period.** Respiratory difficulties may appear at birth (p. 297); though they are largely mechanical or chemical (anoxic) in origin, they may be infectious. Pneumonic infection may occur in utero during prolonged labor, especially when there has been premature rupture of the membranes, or may be acquired during or soon after birth. In some instances pneumonic infections are secondary to disturbances in pulmonary mechanics, as, for example, those resulting from aspiration of large amounts of debris in amniotic fluid or inadequate respiratory excursions in weak, premature or cerebrally damaged infants. Establishment of infection may also be facilitated by congenital anomalies of the upper respiratory tract or of the lungs.

Mechanical disturbances are produced principally by conditions which result in obstruction of the respiratory tract or in depression of the respiratory center. Completely obstructive *malformations* of the respiratory tract are rare; those which cause partial obstruction and may produce laryngeal stridor are not common. One of the infrequent causes of obstruction is *aspiration* of amniotic fluid containing debris such as meconium, epithelial cells and vernix caseosa during the

process of birth. Probably infants aspirate amniotic fluid without ill effect, but when there is asphyxia during prolonged labor, there does appear to be a relation between the pathologic changes and the inhalation of foreign material in the amniotic fluid. The *pulmonary hyaline membrane syndrome* (p. 324) is an important but inadequately understood cause of death in the newborn, especially in premature infants and those of diabetic mothers. *Depression of the respiratory center* may result from direct injury in the area of the medulla or from anoxia (p. 321). Either factor may raise the threshold of stimulation of the respiratory center, resulting in weak and irregular respirations, often with relatively long periods of apnea.

*Atelectasis* is frequent in the newborn infant. Its persistence or secondary occurrence may be facilitated by such conditions as weak respiratory excursions and blockage of the bronchial tree by aspirated material.

**Infancy.** Disturbances of the neonatal period may persist, but this is not particularly common except in cases of congenital laryngeal stridor and of chronic pneumonitis. A pneumonitis which originates within the first few weeks of life and persists should be thoroughly studied for the primary or underlying disturbance. This may be (1) mechanical disturbances related to birth, (2) pulmonary changes associated with cystic fibrosis of the pancreas, (3) stasis secondary to obstructive anomalies within or without the respiratory tract, (4) aspiration of foreign material

such as foreign bodies, food and lipid substances, or (5) a viral infection with secondary bacterial infection.

After the newborn period infection becomes the most important etiologic factor, although it must not be forgotten that this is the age period when aspiration of foreign bodies, of lipid substances and of zinc stearate is at its peak. The common cold takes on added importance because of the frequency of systemic manifestations, the attendant difficulties in nursing due to nasal obstruction, and the high incidence of otitis media and of secondary pneumonia. Throat infections are relatively less frequent than in older children, but the complication of retropharyngeal abscess occurs more frequently. Laryngeal infections more readily cause serious obstruction than in older children, and congenital laryngeal stridor is to a considerable extent limited to the period of infancy.

Pneumonia in infants is a different clinical entity than in children beyond the age of three or four years. The incidence in infants is high; the mortality was excessively so before the introduction of the sulfonamides and antibiotics and is still considerably greater than in older children. During infancy even pneumococcal pneumonias often have a lobular or disseminated distribution in contrast to the frequency of lobar involvement in older children and adults. Pulmonary infections, particularly in infants, can be divided into two groups on the basis of the clinical response. In one the principal clinical manifestation is toxicity; in the other the disturbance is primarily respiratory embarrassment. Both factors, of course, may be and frequently are present in the same infant. The bacterial pneumonias are more liable to produce toxic symptoms in excess of those of respiratory embarrassment; whereas the acute condition variously designated as interstitial pneumonia, bronchiolitis or capillary bronchitis tends, especially in its earlier stages, to cause a disproportionate amount of respiratory embarrassment. Owing to the effectiveness of the

antimicrobial drugs against most of the pathogenic bacteria of the respiratory tract, the incidence and severity of bacterial pneumonias have been greatly decreased. The exception to this situation is the increasing incidence and severity of pneumonia caused by antibiotic-resistant strains of *Staphylococcus aureus* (pp. 344 and 792).

Acute bronchiolitis, asthma, aspiration of amniotic fluid or zinc stearate powder, pulmonary infection associated with cystic fibrosis of the pancreas, and chronic passive congestion secondary to cardiac lesions, as well as widely disseminated bacterial infections, can be responsible for obstructive emphysema and patchy atelectasis. Secondary bacterial infections are frequent complications.

**Childhood.** Respiratory infections gradually take on different characteristics during childhood and eventually, in the preadolescent years, tend to assume the clinical pattern characteristic of the particular infection in adults. The incidence of the common cold increases with entrance to school, but there is less ear involvement and fewer systemic symptoms; even fever becomes relatively uncommon in the latter part of childhood. Throat infections become more frequent, and the tonsil and adenoid problem comes to the fore. The clinical syndromes of acute laryngotracheobronchitis and of acute bronchiolitis are uncommon after three or four years of age; when they do occur, they are clinically less severe. Childhood is the "safe age" of pneumococcal pneumonia; between the ages of four and twelve years the total mortality rate without treatment is only about 5 per cent, and with antimicrobial therapy it is less than 1 per cent. In the latter part of childhood there is a significant increase in the incidence of chronic suppurative lesions, especially of sinobronchitis and, to a less extent, of bronchiectasis. As puberty is approached, the problem of tuberculosis becomes more important, in part because of the stress that physiologic adjustments make upon the growing child.

## THE UPPER RESPIRATORY TRACT

### THE NOSE

#### MALFORMATIONS OF THE NOSE

Congenital anomalies, in contrast to acquired malformations, are uncommon. Such gross anomalies as an accessory nose or complete

absence of the external nose are extremely rare. There may be narrowing of the nasal passages, and occasionally there is complete obstruction of the anterior or posterior nares, more frequently of the latter. Rarely, super-

numery teeth may occur in the nose, or teeth may grow in from the maxilla and be absent from their usual site.

*Choanal atresia* may be unilateral or bilateral; though usually membranous, it may be bony. If it is bilateral, there is difficulty or inability on the part of the infant to suck, and the mouth is constantly open. There may be constant dyspnea, presumably because the infant cannot accommodate to mouth breathing. When the obstruction is unilateral, it may pass unnoticed until infection develops and persists on the affected side with drainage only anteriorly. The obstruction is demonstrated by passing a sound or probe. Bilateral obstructions should be relieved as promptly as possible. Perforation of the membranous obstruction may be performed with direct vision through a nasoscope, but bony obstructions require a more extensive surgical procedure. When the obstruction is unilateral, it is desirable to postpone the operation until the infant is in a satisfactory physical condition and is gaining weight adequately.

*Deviation of the nasal septum* is more often an acquired than a congenital condition and is not common in young children. If at all possible, operation should be deferred until the child is fourteen or fifteen years of age. If operative correction seems imperative before this age, a method should be used which preserves the septal tissues, since, otherwise, external deformities of the nose may result. Perforation of the nasal septum is more likely to be due to such infections as syphilis or tuberculosis than to congenital defects. Malformations of the septum, of the floor of the nose and even of the external nose are frequently associated with harelip and cleft palate.

An *encephalocele* protruding through a defect in the cribriform plate into the nasal cavity is a rare anomaly, but should be differentiated from polyps and tumors of extracranial origin.

## FOREIGN BODIES IN THE NOSE

Foreign bodies of various sorts such as peas, cherry stones and beads are frequently introduced into the nose in early childhood. Larvæ of flies are occasionally deposited in the nose. The foreign body is situated at first well forward, but unskillful efforts of the patient or others to remove it may push it farther inward. The early symptoms are obstruction to respiration, pain and, perhaps, sneezing from the local irritation. If the object is

smooth and hard and not liable to swell by absorption of liquid, it may remain for weeks or months without producing other symptoms. Generally, however, evidences of increasing irritation soon develop, with swelling of the mucous membrane, increasing obstruction and a purulent bloody discharge. The fact that the discharge and other symptoms are unilateral strongly suggests the presence of a foreign body, and examination with a speculum or nasoscope is indicated. forcible blowing of the nose with the unaffected nostril compressed is sometimes effective if the object has been present for only a short time. When the foreign body is more securely lodged, the nasal cavity should be sprayed with a local anesthetic before removal under direct vision is attempted.

## NEOPLASMS OF THE NOSE

The most frequent nasal growths are polyps (see *encephalocele*, above). They produce obstructive symptoms and are often associated with chronic nasal discharge and allergic rhinitis. Treatment consists in their removal and in attention to the chronic rhinitis and/or any allergic factor. Neoplasms are rare in early life and are described on page 1347.

## EPISTAXIS

**Etiology.** Nosebleed is rare in the neonatal period and in infancy, is common in childhood, and decreases in incidence after puberty. Rhinitis, foreign bodies, polyps, external trauma, forcible blowing and picking of the nose may be inciting causes. A persistent, bloody, purulent nasal discharge is a characteristic manifestation of nasal involvement in syphilitic and diphtheritic infections. Adenoid overgrowths may be associated with congestion which incites nasal bleeding. Varicosities or telangiectases of the mucous membrane of the septum, at times associated with a small area of ulceration, are frequent factors in recurrent bleeding. The strain of physical exercise or mental excitement in children with a local nasal lesion may be sufficient to instigate nasal bleeding. Any condition (cardiac, vascular, renal or emotional) which causes elevation of the blood pressure may be responsible for nasal hemorrhage; during the active phase of rheumatic fever there is frequently epistaxis with or without hypertension. Nasal bleeding may occur in association with any of the blood

dyscrasias, and occasionally is associated with a variety of infectious diseases such as typhoid fever, diphtheria, scarlet fever, measles, influenza and malaria. Near the age of puberty it is not infrequent in girls, when it may constitute vicarious menstruation.

**Clinical Manifestations.** Usually the hemorrhage comes without warning, and the blood flows slowly from one nostril or sometimes from both. Exceptionally, it may be in large amount, especially in some of the systemic hemorrhagic diseases, and it may even be fatal. When it occurs at night, the blood may be swallowed and the diagnosis made only from the vomiting of blood or its passage in the stools or by rhinoscopic examination. Generally an attack of epistaxis stops spontaneously.

**Treatment.** The child should be kept as quiet as possible in a semi-erect position, have the clothing around his neck loosened, and be cautioned against blowing his nose. An ice bag may be applied over the bridge of the nose. A few drops of a solution of epinephrine (1:1000), with or without 1 per cent cocaine added, may be applied to the nasal mucous membrane with a cotton applicator. It may be possible to detect the bleeding area and to cauterize it with silver nitrate. Packing the nares is necessary in more severe instances; Gelfoam may be used. Blood transfusion may be indicated if much blood has been lost. Rarely it becomes necessary to ligate the internal maxillary arteries or even the carotid. An attempt should be made to determine the underlying factor.

## ELONGATED UVULA

Persistent enlargement of the uvula is rare; it may be congenital or may result from a chronic upper respiratory tract infection. The long uvula coming into contact with the base of the tongue produces an annoying cough and a constant desire to clear the throat.

These symptoms tend to be exaggerated when the child is lying on his back. Enlargement associated with chronic infection may disappear with eradication of the infection. Otherwise, amputation of the tip of the uvula may be indicated.

## INFECTIONS OF THE UPPER RESPIRATORY TRACT

### GENERAL CONSIDERATIONS OF ACUTE INFECTIONS

Infections of the upper respiratory tract constitute a major segment in the illnesses of infants and children. The epidemiologic aspects are more important in acute infections than in chronic ones. Acute infections tend to be widespread in a group, be it family, school or community. Understanding of a specific acute infection is related to identification of the etiologic agent, when possible, its means of spread, and the variations in its clinical patterns. By contrast, the problems of chronic respiratory disease are to a much greater extent centered in the individual patient and include such factors as susceptibility to infection, anatomic abnormalities of the nasopharynx, allergy, and perhaps other factors related to chronic involvement of tonsils, adenoids and sinuses.

Acute infections may be caused by viruses or bacteria; nearly all the acute infections of the nose and nasopharynx are caused by viruses. Although bacteria are more fre-

quently responsible for pharyngeal and laryngeal infections, most of the acute infections in these areas are also of viral origin.

### ETIOLOGIC CONSIDERATIONS OF NEWLY ISOLATED VIRUSES

More new viruses are being associated with infections of the respiratory system than there are well defined clinical and epidemiologic entities with which to match them. In recent years at least nine viruses or groups of viruses other than influenza have been reported as possible causes of respiratory tract disease. These include the large group of adenoviruses, the group A Coxsackie viruses, certain miscellaneous viruses such as the respiratory syncytial virus, "2060" virus, JH virus and an ECHO virus, "JV-1," as well as the following myxoviruses: the croup-associated virus, the hemadsorption viruses and Sendai virus (newborn pneumonitis virus, hemagglutinating virus of Japan or influenza D). All these

agents have been recovered from the respiratory tracts of children or adults during respiratory infection. However, more is known about some than about others in their etiologic relation to respiratory tract illness.

The adenoviruses, for example, are extremely common inhabitants of the respiratory tract; the group includes the cytopathogenic agents which were originally isolated from tonsils and adenoids, and other related viruses which have subsequently been found in cases of conjunctivitis and pharyngitis and from fecal material and certain tissues at necropsy. There is good evidence that one of the adenoviruses, type 3, causes so-called *pharyngoconjunctival fever*, an acute illness characterized by fever, pharyngitis, conjunctivitis and posterior cervical lymphadenopathy. Adenoviruses types 4 and 7 have been established as causes of an acute febrile disease of the respiratory tract in military recruits characterized by fever, chills, headache, generalized aches and pains, hoarseness and irritation of the throat. The clinical pattern is considered relatively specific by those dealing with military personnel. Types 4 and 7 viruses have rarely been isolated from children. Apparently adenoviruses types 1, 2, 3, 4, 5 and 7 may cause pharyngitis, but sufficient cases have not been reported to allow a full clinical description. These viruses, particularly types 1, 2 and 5, have been found in up to 90 per cent of tonsils and adenoids removed surgically in several parts of the world. This observation permits the speculation that after an acute infection with adenoviruses a person may harbor the virus in a "latent" state for an indefinite time.

The clinical relation of group A Coxsackie viruses to a particular type of vesicular pharyngitis in children, herpangina (p. 528), is now well accepted.

Two myxoviruses, hemadsorption virus, types 1 and 2, have recently been identified, and controlled studies strongly suggest that they may be common causes of respiratory tract disease in children. In one study up to 33 per cent of infants with a "croup syndrome" were infected with type 2 hemadsorption virus.

Clinical and epidemiologic studies on the other viruses mentioned have not been of an order to permit definitive deductions about the frequency with which they cause respiratory tract disease. The croup-associated agents have been isolated in several parts of the world from children with croup as well as

from children with other manifestations of respiratory tract illness. In one survey 90 per cent of adults had hemagglutination inhibition antibodies against these viruses. Sendai virus has been found in association with pneumonitis in infants, a meningitis-like syndrome in infants, and an influenza-like illness in adults. This agent is serologically related to hemadsorption virus, type 2, by complement fixing, but not by hemagglutination inhibition and antibody neutralization tests. Limited data suggest that the respiratory syncytial virus, identical with a causative agent of coryza in chimpanzees, may be a causative agent of bronchopneumonia. Similarly, ECHO virus, JV-1, has been related to mild respiratory illness. In two different outbreaks the "2060" virus was recovered from naval recruits with mild respiratory illness, and sixteen of forty-seven affected patients showed a rise in neutralizing antibody to this virus in their serums after the illness. The prevalence of antibody to "2060" virus increases with advancing years. JH virus has been described in association with symptoms of low grade fever, malaise, coryza, sore throat and a cough; 20 per cent of serums from persons over the age of eight years contained neutralizing antibodies to this virus. There is some evidence to suggest that the "2060" virus and JH virus are serologically related to each other.

It would appear that a number of newly isolated viruses may affect the upper respiratory tract in a common way. A great deal of combined clinical, laboratory and epidemiologic study is necessary before the clinical patterns produced by these recently identified viruses, as well as by those yet to be identified, can be adequately defined.

In spite of the frequency and importance of acute infections of the upper respiratory tract, it is impossible to identify many of them as distinct clinical entities. This is not surprising, since the tissues of the nose, pharynx and larynx, as well as those of the tracheobronchial tree, are in direct continuity, and they connect with the paranasal sinuses and middle ear. Further, all these structures have limited ways in which they can respond to noxious agents of any sort. Although some infecting agents tend to have a predilection for certain portions of the respiratory tract, most of them tend to produce symptoms in the several anatomic divisions of the upper respiratory tract, often in descending order.

For clinical purposes it is deemed advisable

to classify respiratory infections on the basis of their principal location as rhinitis, nasopharyngitis, pharyngitis or laryngitis.

### ACUTE NASOPHARYNGITIS

(THE COMMON COLD, UNDIFFERENTIATED ACUTE RESPIRATORY DISEASE AND OTHER VIRAL INFECTIONS)

The designation "acute nasopharyngitis" is used principally as a substitute for the clinical designation "the common cold." This infection, which characteristically involves the nasal accessory sinuses as well as the nasopharynx during the acute phase, is the most frequent one of infants and children. Its importance in pediatric practice depends not only upon this factor, but also upon the frequency with which serious complications result. The clinical pattern of the "common cold" in infants and small children is quite different from that in older children and adults.

**Etiology.** It seems likely from the work of Dochez and others that the common cold is a specific contagious disease caused by a filtrable virus or a group of viruses responsible for the initial catarrhal symptoms and for transmission of the disease. The characteristic secondary purulent stage is, in turn, produced by bacterial invaders. Though this latter phase may be a means for dissemination of pathogenic bacteria, the infective period of the cold, *per se*, is apparently limited to some hours before and to only a day or two of the initial phase.

Secondary bacterial invaders are apparently responsible for the purulent stage of the common cold, and perhaps to a large extent for the complications in the sinuses, ears, mastoids, lymph nodes and lungs. The more frequent bacterial invaders are the Pneumococcus, the hemolytic Streptococcus, *H. influenzae* and the Staphylococcus, the last especially in small infants.

**Contributory Factors.** A number of factors appear to have contributory roles in the development of colds, but their relative importance is not clear. There appears to be a variation in *susceptibility* even in infants. But often what appears to be an increased susceptibility may represent frequent exposure to infection or acute exacerbations of a chronic infection.

Age is a factor in severity and complications, but the evidence of its relationship to susceptibility is less definite. It has been stated that there is an insusceptibility to colds

in the neonatal period and that not until four to six months of age does the infant have a high susceptibility. It may be that the low incidence among newborn infants mainly reflects the relative infrequency of their exposure; infection does occur at this age.

The state of *nutrition* would appear to be a greater factor in determining severity or the development of complications than in affecting susceptibility to infection.

Dust or other *irritants*, including specific allergens, may produce sneezing and a copious watery nasal discharge, but this is not to be confused with the common cold.

**Chilling** of the body, exposure to cold and dampness, and wet feet have long been associated with nasal disturbances. They do have a vasomotor effect and reduce the temperature of the nasal mucous membrane by several degrees. Initially there is a vasoconstriction followed by a period of vasodilatation. Under such circumstances many persons have such symptoms of nasal irritation as sneezing and serous discharge, and those with chronic infections might well have exacerbations. If the "cold" virus were a recent invader, the effects of exposure would most likely be distinct contributory factors.

**Fatigue** and *emotional disturbances* may also temporarily lower resistance.

**Epidemiology.** There is practically universal susceptibility to acute nasopharyngitis, and it has been estimated that the incidence in children is three to six attacks a year. Infections tend to occur in cycles with several peaks of incidence during the year. The first of these occurs shortly after the opening of school in September and October, another in January and February, and a third in April and May. The incidence is highest during periods of increased housing and the school term.

**Pathology.** Initially there is only edema of the submucosa, quickly followed by infiltration with leukocytes which are principally mononuclear at first, with polymorphonuclear cells predominant by the second or third day. There is separation and sloughing of the epithelial cells, with the result that practically the entire nasal epithelium is destroyed. After the acute phase the remaining epithelium proliferates, and the epithelial surface is renewed.

**Clinical Manifestations.** The clinical pattern in infants and small children differs from that in older children and adults. In the first two or three years of life, except perhaps in the first month or two, fever is a

prominent symptom, whereas in older children, especially after eight to ten years of age, the clinical course simulates that of adults and is usually afebrile, or at most there is only a low grade fever. Young children are also more prone to complications, especially otitis media and pneumonia, so that the "cold" problem is a serious one in the first few years of life. Persistent infection of the sinuses is, however, more frequent in older children than in infants.

**In older children.** Characteristically, the initial symptoms are dryness and irritation in the nose and, at times, in the pharynx. This is followed within a few hours by chilly sensations, muscular aches, sneezing and a watery nasal discharge. Headache, general malaise, anorexia and low grade fever in varying combinations may be present. Within one to three days the secretions become thicker, and eventually purulent. The discharge is irritating and reddens the edges of the nostrils and the upper lip. The nasal obstruction makes mouth breathing compulsory, and the drying effect on the throat increases the sensation of soreness. The duration of the acute phase varies from one to two weeks.

**In infants.** The onset in the infant is usually characterized by fever, in which the temperature may be 102° to 104° F., and by irritability and restlessness. The local manifestations are similar to those described for the older child with the addition of vascular congestion of the eardrum in most instances during the first day or two whether or not there is otitis media subsequently. Interference with sucking becomes a problem because of the nasal obstruction. Fever may be present only at the onset, or may last two or three days and return again if there are purulent complications. Vomiting is not uncommon, and mild diarrhea may be a manifestation. In the newborn infant the general manifestations, especially the fever, may be less marked.

**Differential Diagnosis.** The principal conditions to be considered in the differential diagnosis are the initial phases of certain of the acute contagious diseases, influenza, acute exacerbations of chronic upper respiratory tract infections, allergic rhinitis, vasomotor responses to cold and exposure, and, in young infants, syphilis.

The initial manifestations of *measles* and *pertussis* in particular and, to a less extent, of *poliomyelitis* are those of nasopharyngitis. *Scarlet fever* and *pharyngeal diphtheria* are less likely to be confused with "the common cold," since their respiratory symptoms are

predominantly pharyngeal. When there is a persistent nasal discharge, bloody or otherwise, in the first few months of life, the possibility of *congenital syphilis* must be considered, and that of *nasal diphtheria* at any age.

The milder cases of viral *influenza* of the respiratory type may be indistinguishable from other forms of nasopharyngitis, although as a rule influenza is attended with a degree of prostration out of proportion to the respiratory symptoms.

**Allergic rhinitis** should always be considered when there are frequent "colds." If the nasal discharge does not proceed to the purulent stage, an allergic etiology is likely, but the possibility of allergy is not eliminated even when there are frequent or persistent attacks of purulent rhinitis. The demonstration of large numbers of eosinophilic cells in the nasal secretions and a distinct pallor of the nasal mucous membrane are suggestive evidence in favor of allergy, but the proof rests in the detection of the specific allergen and improvement following its removal or antiallergic treatment.

**Complications.** The principal complications occur by direct extension from the nose with involvement of the accessory sinuses, ears, mastoids, throat, larynx, bronchi and lungs. Slight enlargement of the cervical lymph nodes is common; less often it is extensive, when there may be suppuration. *Middle ear infection* of some extent occurs with a high degree of regularity in infants and small children, but is less frequent in older children. Direct visualization of the eardrum is an essential part of the examination of the infant with the common cold, especially when the fever continues high after the first day or two or when there is a recurrence of it. *Bronchitis* and *pneumonia* not only occur more frequently in infants than in older children, but are also more serious. In children who have a tendency to spasmodic laryngitis acute nasopharyngitis is an effective trigger mechanism. The *paranasal sinuses* are probably involved in all nasal infections; persistence of the infection in them after the acute phase is not common, but is more frequent in older children than in infants.

**Prevention.** There is no adequate means for the prevention of epidemic nasopharyngitis other than that of avoidance of contact with an infected person. In older children and adults such prevention is practically impossible. Some degree of isolation can be provided for the infant, however, and every

effort should be made to lessen his chances for infection, owing to the relative severity of the infection in this age group. Vaccines are of no value, nor is there any evidence that so-called hardening processes are effective.

**Treatment.** Treatment is symptomatic. There is no need for antimicrobial therapy except when complications develop, and their use otherwise is not advisable.

Rest in bed is advisable during the febrile period. Sleep, especially in infants and small children, may be disturbed by the fever and by nasal obstruction. Aspirin is often helpful in reducing the restlessness of infants as well as the aching and malaise of older children. It may be prescribed in doses of 60 mg. (1 grain) per year of age up to five years with doses of 0.3 gm. (5 grains) in older children, two or three times a day, for the first day or two of the infection. Excessive and protracted use should be avoided, especially in infants, owing to the danger of salicylate intoxication. A barbiturate to induce sleep is rarely necessary if the nasal obstruction is relieved.

Though nasal instillations have been much abused, they do have merit. The provision of a patent nasal airway not only decreases the restlessness, but makes it possible for the child, and especially the infant, to eat more satisfactorily. Ephedrine in aqueous solution, preferably a buffered one, or one of the many commercial ephedrine or ephedrine-like nasal solutions may be given. Solutions of one-half to one-quarter the strength for adults should be prescribed for infants and small children. Oily vehicles should be scrupulously avoided, owing to the danger of lipoid pneumonia; preparations containing sulfonamides and/or antibiotics are not recommended. Instillation of the drops should be done only when there is obstruction, not oftener than every three hours, and such frequency should not be continued for more than two or three days. A good plan is to instill the drops fifteen to twenty minutes before feedings and at bedtime. Often a single instillation produces shrinkage of the mucous membrane only in the anterior part of the nasal cavity; if a second instillation is made within five or ten minutes, it may increase the effectiveness by shrinking the posterior part. When the edema of the mucous membrane is marked, better results may be obtained by introducing the shrinking solution as far as the nasopharynx on a cotton-wrapped flexible metal applicator which is permitted to remain in position for a few minutes. Care should be taken that the

cotton extends beyond the anterior nares when the applicator is completely inserted. The Proetz or Parkinson displacement techniques may be used in older children. Bottles containing nose drops should not be used for more than one person, nor for more than one infection, since they may become contaminated with bacteria and be a source of secondary infection. Older children may use inhalers if their frequent and prolonged use is avoided.

Nasal drainage is a problem in infants, since they cannot "blow their noses." Best drainage is provided by placing the infant on his abdomen, provided this position does not tend further to embarrass respiration. Raising the head of the bed facilitates anterior drainage somewhat, but increases the likelihood of pulmonary aspiration and hence of pneumonia; for this reason it is preferable to raise the foot of the bed. Various types of suction apparatus, both intranasal and extranasal (with suction cups), have been used, but they are annoying to the infant, not very effective and not without danger. The humidity of the air should be maintained at a high level, preferably 80 to 90 per cent.

Both infants and children tend to have some loss of appetite and should be permitted to determine the amount of food taken and, to a considerable extent, the type. Attempts to force food at such times are a frequent cause of persistent feeding difficulties. Purgation is to be condemned, and cathartics are to be prescribed only when definitely indicated. Fluids, including fruit juices, should be offered frequently, but forcing them has no merit. The intake of water-soluble vitamins should be maintained at usual levels.

A convalescent period of a few days after the acute phase is to be commended, but unfortunately is not common practice. Isolation of the child is important not only to protect others, but also to lessen the chances of secondary infection of the child himself. The treatment of such complications as otitis media, sinusitis and pneumonia is discussed under their respective headings.

## ACUTE PHARYNGITIS

### BACTERIAL AND NONBACTERIAL (VIRAL)

Acute infections of the throat are not common in the first year or so of life, but occur frequently thereafter. Though there is some degree of throat involvement in all acute upper respiratory tract infections, including "the common cold," the various grippal infec-

tions and most of the acute contagious diseases, the conditions under discussion here are those in which the principal involvement is in the throat. Because they are discussed in detail elsewhere, diphtheria, scarlet fever, herpangina and infectious mononucleosis are not described here.

**Etiology.** In the past acute throat infections were considered to be bacterial in origin, with members of group A hemolytic *Streptococcus* responsible for most of them. Clinical, bacteriologic and epidemiologic studies now indicate that nonbacterial agents, presumably viruses, are responsible for the majority of pharyngeal infections. Clinically, certain distinctions between bacterial and nonbacterial throat infections have been described, but they do not permit an etiologic diagnosis. When, however, a preponderance of a pathogen such as the beta hemolytic *Streptococcus*, group A, the *Pneumococcus* or type b *H. influenzae* is demonstrated in a bacterial culture early in the course of the disease, and when the clinical findings are compatible and there is a polymorphonuclear leukocytosis, an etiologic diagnosis is justified. Except for group A Coxsackie viruses in herpangina, adenovirus type 3 in pharyngoconjunctival fever and adenovirus types 1, 2, 3 and 5 in some cases of pharyngotonsillitis, viral agents have not been identified, and the evidence that they may be responsible for exudative lesions of the pharynx and tonsils is indirect.

**Clinical Manifestations.** *Nonbacterial exudative tonsillitis and pharyngitis* is generally a mild disease of short duration. In contrast to the typical case of bacterial pharyngitis, the onset tends to be gradual, the more common early complaints being feverishness, headache and anorexia. Sore throat, hoarseness and cough, often productive, are present in the majority of patients and tend to be at their peak by the third or fourth day of illness. Evidences of inflammation are not severe as a rule. There are moderate degrees of vascular injection and often a follicular type of exudate, in which the individual lesions usually do not coalesce. The exudative lesions may be situated on the individual lymphoid follicles on the posterior pharyngeal wall as well as on the faucial tonsils. Cervical lymphadenopathy may occur, but suppuration does not unless there is secondary bacterial infection. Pulmonary involvement is not common. Leukocyte counts are usually below 10,000 per cubic millimeter with normal differential distributions. Fever usually does not exceed 101° to 102° F. and declines

by lysis, the total duration of the febrile course being three to five days. Complications are infrequent.

In contrast, the onset of *bacterial pharyngitis and tonsillitis* is generally acute, and initially there may be only fever, which tends to be high (102° to 105° F.). Throat symptoms and signs are frequently absent for the first twelve to twenty-four hours, and commonly the complaints or physical findings at this time are inadequate to provide a clue to the diagnosis. There may be headache and vomiting and frequently a general grippal sensation. If the tongue is coated and the papillae are swollen, as they frequently are at this stage, it is impossible to differentiate an acute pharyngitis from the prodromal stage of scarlet fever. Initially, there may be a feeling of dryness in the throat, but actual pain is inconstant. Pharyngeal pain is usually noted by the end of the first day, but its degree varies considerably. It may never be mentioned, or it may be so excruciating that swallowing and speaking are affected. In general, the systemic manifestations tend to become less marked as the throat signs become apparent. In the milder cases the temperature returns to normal within one to three days, and the local manifestations do not persist much longer, but in the severe cases the course may extend for a week or two. The appearance of the throat varies from a moderate inflammatory injection of the tonsils or tonsillar fossae, the pharynx and soft palate to a fiery redness and swelling of these tissues with exudative lesions. The latter may consist of many small areas of exudates (follicular tonsillitis), or there may be one or more relatively large membranous areas. Cervical lymphadenopathy is present in most instances.

The term *streptococcosis*, coined by the Yale group in the 1940's, although not widely adopted as a diagnostic term, does imply descriptions of streptococcal disease in childhood which are worthy of perpetuation. In general it is suggested that infection with the beta hemolytic *Streptococcus* in a manner somewhat analogous to tuberculous infection has its clinical manner of expression altered by an initial invasion of the individual host. Since effective contact with this organism is so frequent, it is postulated that the first infection is most likely to occur within the first few years of life. Subsequent to this first infection (sensitization), the clinical reactions to streptococcal disease tend to be localized, particularly in the throat, with acute manifes-

tations of relatively short duration ("strep throat"). Scarlet fever with its expression of the erythrogenic toxin is included in this secondary infectional pattern, and glomerulonephritis and rheumatic fever are considered systemic manifestations of it. The obvious question in this hypothesis is whether initial infection with one strain of beta hemolytic *Streptococcus* group A will alter the reaction pattern to subsequent infections with other strains.

The following is the description of the clinical patterns by Powers and Boisvert:

In the simplest form, the infant under 6 months shows irregular fever, under 102° F., a thin mucoserous nasal discharge causing some excoriation and crusting around the nostrils and some pharyngeal injection. There may be slight vomiting and diarrhea early in the course and loss of appetite. The acute episode may last less than a week and except for persisting nasal discharge the patient may seem only somewhat peaked and slightly indisposed for . . . five or six weeks. Sometimes the disease, like primary tuberculosis, is almost asymptomatic with little or no complaint.

In the form most frequently demanding medical attention . . . the patients are children between 6 months and 3 years of age; they are more severely ill than those just described. The early symptoms and signs are those of coryza with postnasal discharge, a diffusely reddened pharynx, fever, vomiting, and loss of appetite. For a few days the temperature curve shows elevations of from 100 to 103° F. and continues, in typical cases, to be irregular for . . . four to eight weeks gradually becoming normal. Within a few days of onset the cervical glands begin to enlarge; they are usually modest in size and moderately resistant in consistency, there is some tenderness and pain when the mouth is opened. The course of the adenopathy follows roughly the fever with subsidence in about six weeks in the typical case. This is one of the several "glandular fevers" and "catarrhal fevers." However, marked swelling, reddening, softening, and suppuration may occur at any time in the six weeks' course; this complication is usually unilateral. Catarrhal otitis media, like persisting cervical adenopathy, is so frequently an accompaniment of streptococcal upper respiratory infections in infants that the conditions in some form may be regarded . . . as integral parts of the disease rather than as complications.

These patients have a pasty pallor and are anorectic; they lose weight and are unhappy and querulous; convalescence is slow and return to health often a matter of months. The four to eight weeks' subacute febrile illness and prolonged convalescence constitute outstanding clinical characteristics of the disease.

**Diagnosis.** Bacterial and nonbacterial tonsillitis and pharyngitis cannot be distinguished except as indicated under Etiology by bacterial cultures and other findings. The presence of an epidemic of a particular type of

infection is of course of some benefit in evaluation of the individual patient. The response of the disease to antibacterial therapy is also of limited value in differential diagnosis. Ideally, a throat culture should be obtained in each instance, but this is not practical. When there is a membranous exudate, a culture is necessary in order to eliminate the possibility of diphtheria. Though the onset of acute nondiphtheritic pharyngitis is characteristically more abrupt, the fever higher, and the pseudomembrane more likely to be limited to the tonsillar area, the clinical impression should be supported by bacteriologic data. The throat in infectious mononucleosis may also have a similar appearance. Scarlet fever presents the greatest difficulty, and, until the rash appears, it may be impossible to make a distinction. In herpangina there are characteristically many vesiculoulcerative lesions with an erythematous areola on the anterior pillars, fauces and soft palate.

**Complications.** The inflammation of the cervical and retropharyngeal nodes may proceed to abscess formation. Uncommonly there is an agranulocytosis associated with ulcerative and gangrenous throat lesions (*agranulocytic angina*). Especially in malnourished and debilitated children, there may be secondary and prolonged ulcerative throat lesions from which fusospirochetal organisms may be obtained in large numbers; whether they have a pathogenic role is not established. Peritonsillar abscess is an occasional complication, as are pneumonia, sinusitis, otitis media and meningitis. Acute streptococcal throat infections are the precipitating cause of acute glomerulonephritis and of initial and repeat attacks of rheumatic fever. For this reason the urine should be examined weekly for three weeks after the acute phase of the throat infection, and the child should be observed for manifestations of rheumatic fever. Acute mesenteric adenitis with symptoms of abdominal pain and vomiting is an occasional complication and, when the pain is in the right lower quadrant, may simulate appendicitis.

**Treatment.** For nonbacterial infections the treatment is symptomatic. In proved or suspected bacterial infections, most of which are caused by group A beta hemolytic streptococci, penicillin is the drug of choice and should be given for about ten days. Ideally, the child should be kept in bed during the acute phase and should be isolated. Either hot or cold compresses or ice or hot water bags may be placed about the neck, the choice

(usually cold) depending upon the child's preference. Aspirin is a satisfactory drug for the relief of pain and general discomfort. Dosages may be calculated on the basis of 60 mg. (1 grain) per year of age. Adequate fluid intake should be maintained, but no effort need be made to force the child to eat. The diet should be soft, and chilled or hot substances are as a rule more easily swallowed than those at room temperature.

There are no practical measures for prevention of pharyngeal infection other than isolation and avoidance of contact with known active cases. Sulfonamide or penicillin prophylaxis, however, is justified for children who have had rheumatic fever.

### RETROPHARYNGEAL ABSCESS

This infection is a suppurative lesion in one or more of the retropharyngeal lymph nodes, which is usually secondary to a nasopharyngeal infection. Retropharyngeal abscess is relatively uncommon after the first few years of life. Its incidence has decreased in recent years along with that of other suppurative lesions secondary to respiratory infection. Rarely, the infection may be introduced by a penetrating foreign body, as, for example, a fish bone.

**Clinical Manifestations.** In the well developed case the manifestations are fairly characteristic. The onset is more or less abrupt, following an acute upper respiratory tract infection. There is difficulty in swallowing, and the infant lies with his head retracted or to one side and his mouth open. Respirations are noisy, often gurgling. Fever is usually high, and prostration is likely to be marked. On visual examination the bulge of the posterior pharyngeal wall is apparent if it is situated high in the pharynx.

Digital examination provides more definite information and usually reveals the mass to be greater on one side; the tongue is gently depressed with a tongue blade, and the finger is inserted from the angle of the mouth onto the base of the tongue and into the pharynx. A gag is not necessary. The infant rarely has teeth in the lateral portions of the gums during the age when retropharyngeal abscess is common, and introduction of the finger into the pharynx reflexly keeps the mouth open. The entire procedure should be performed quickly and gently, since not only is the child disturbed by the examination, but also serious damage can be done.

Infrequently the pus may burrow down the

vertebral column, and the bulge of the abscess is then sufficiently low that it is shown only on a lateral roentgenogram. The mass in the pharyngeal area is also demonstrated on a lateral roentgenogram. The roentgenogram does not, of course, provide any indication of whether suppuration has taken place. Non-fluctuant lymphadenitis in the retropharyngeal area may produce shadows similar to those of suppurative lesions. Retrogression of nonsuppurative adenitis is not unusual, and the decision for drainage can be based only on the presence of fluctuation revealed by digital examination.

Suppressive antimicrobial therapy may alter the course significantly. One case with abscess formation of a month's duration has been reported in which the principal complaints were pain on swallowing and stiffness of the neck.

*Cervical caries* may be responsible for a retropharyngeal abscess. Although this is uncommon in infancy, it must be considered in the differential diagnosis. In such cases the onset is less abrupt, the course is longer, the abscess is more medial, there is greater stiffness of the neck, and there are likely to be other signs of spinal involvement.

**Course and Prognosis.** If the abscess is incised as soon as fluctuant, and appropriate antibacterial therapy is given, the prognosis is good. The abscess may rupture externally on the side of the neck or into the esophagus, mediastinum or auditory canal; facial paralysis results from the last complication. The majority of deaths occur in previously unrecognized cases, and sudden death may be caused by edema of the glottis, pressure upon the larynx, rupture into the larynx, or erosion of blood vessels with severe hemorrhage. Other causes of death are pneumonia and pulmonary abscess. When the abscess is secondary to cervical caries, the course is slower, and after operation reaccumulation of pus is likely. There is also greater tendency to burrow, but less danger of asphyxia.

**Treatment.** Antibiotic therapy should be prescribed immediately. If the child is seen before suppuration has occurred, retrogression is often obtained without abscess formation. When the abscess becomes fluctuant, it should be opened, preferably without general anesthesia. After the child has been wrapped firmly in a sheet a gag should be inserted and the head of the operating table lowered to prevent aspiration of the discharging pus. A puncture incision is made where the abscess is pointing, and the pus is removed by suc-

tion. When the abscess has been evacuated, the incision may be lengthened slightly to permit proper drainage. Suction of the pharynx should be carried out frequently after the operative procedure. Should the incision close and an abscess form again, it will have to be reopened. Before the incision is made, however, the fluctuant mass should be aspirated to make sure that hemorrhage has not occurred from erosion of one of the branches of the carotid artery. Incision in such a case might well result in a fatal hemorrhage. When there is active bleeding, the carotid artery, in spite of the possibilities of serious cerebral sequels, may have to be ligated.

### PERITONSILLAR AND RETROTONSILLAR ABSCESES

In contrast to retropharyngeal abscess, peritonsillar and retrotonsillar abscesses (quinsy) are uncommon during infancy and less common during childhood than in young adulthood. The term *peritonsillar* abscess is used for suppurative lesions situated mesial to and in front of the tonsil and usually adjacent to the upper pole, so that the tonsil is pushed backward and the uvula is displaced to the opposite side; the *retrotonsillar* abscess, which is directly behind the tonsil, pushes the tonsil outward into the throat and makes it more prominent. Any of the common pyogenic bacteria may be causative, but the hemolytic *Streptococcus* is the most frequent one. Only rarely do such abscesses occur in children whose tonsils have been removed. Repeated attacks may occur if the tonsils are not removed.

**Clinical Manifestations.** The abscess usually occurs with or follows closely an acute tonsillitis or pharyngitis. If the initial fever has subsided, there is a secondary elevation of temperature ( $103^{\circ}$  to  $105^{\circ}$  F.), and the subsequent course is septic. The pain in the throat is severe and out of proportion to that usually observed in acute throat infections. Difficulty in opening the mouth is a characteristic symptom of peritonsillar abscess, and swallowing and speaking are usually impaired. The pain may radiate to the ear of the affected side, and there may be torticollis with the head turned toward the side of the abscess. Inspection during the early stage shows little except a unilateral prominence in the tonsillar region, but palpation reveals a hard, swollen and tender mass. As the process advances, the affected tonsillar area becomes more prominent, the mucous mem-

brane is red and swollen, and the edematous uvula is displaced to the opposite side of the throat. After several days or a week the abscess points, and fluctuation is demonstrable generally in the region of the anterior faucial pillar. The inflammation may subside without abscess formation when effective antibacterial therapy has been started early. When there is an abscess, spontaneous rupture occurs if it is not incised. Complications are not common, although severe hemorrhage, edema of the glottis and extension of the suppurative process into the neck have been observed.

**Treatment.** Before suppuration has occurred, treatment consists in the local use of an ice bag or hot compresses, hot water bottle or a heating pad, depending upon the preference of the child; such analgesic drugs as aspirin and/or codeine, and full dosage of penicillin or a broad-spectrum antibiotic. When suppuration is present, the abscess should be incised. It is preferable to open the abscess rather than allow it to rupture spontaneously, but one should await definite fluctuation before making the incision. After the abscess has ruptured or has been incised, warm saline irrigations may aid in keeping the oral cavity clean and provide some relief from the discomfort. Three or four weeks after the inflammation has subsided the tonsils should be completely removed in order to prevent subsequent attacks. At this time the prophylactic administration of an antibiotic is indicated.

### SINUSITIS

The maxillary antrums and the anterior and posterior ethmoid cells are present at birth and are usually of sufficient size to harbor infection. Each of the frontal sinuses develops from an anterior ethmoid cell. Though invasion of the frontal bone and pneumatization of the sinuses are demonstrable some time during the first two to four years of life, the frontal sinus is rarely a site of significant infection until the sixth to the tenth year. When there is severe ethmoidal disease in the first few years of life, the development and pneumatization of the frontal sinuses may be curtailed or even completely prevented. The sphenoidal sinus is present at birth; though there are variations in its development, it usually does not assume clinical significance until the third to the fifth year of life.

It can be assumed that the paranasal sinuses are involved in practically all acute nasal infections, but, as a rule, the sinus in-

involvement does not persist after the nasal infection has subsided unless there has been a pre-existing sinus infection. The incidence of both acute and chronic sinus infections increases in the latter part of childhood.

#### ACUTE SINUSITIS

In addition to the general involvement of the sinuses during acute nasal infections, there may be acute empyema of one or more sinuses of sufficient severity to dominate the clinical picture. Serious sinus involvement may occur during acute nasal infection or follow it closely.

**Clinical Manifestations.** The symptoms of acute sinusitis, in addition to those of rhinitis, are fever, localized pain, tenderness or a sense of fullness, headache and, at times, edema over the affected sinus. So-called sinus headaches, which tend to involve the region of the affected sinus, may assist in localization. In sphenoidal sinusitis the headache may be in the suboccipital region; in anterior ethmoidal sinusitis, in the region of the temples and over the eyes; and in posterior ethmoidal sinusitis, over the distribution of the trigeminal nerve, especially over the mastoid area. Unless the sinusal ostia are obstructed, there is a purulent discharge which can be observed directly through a nasoscope. Pus in the middle meatus suggests involvement of the maxillary, frontal or anterior ethmoid sinuses; in the superior meatus, of the sphenoid or posterior ethmoid cells.

In acute ethmoiditis, especially in infants and small children, periorbital cellulitis with edema of the soft tissues and redness of the skin is a common manifestation.

**Diagnosis.** The roentgenogram will reveal an opaque shadow when a frontal or maxillary sinus is filled with pus, but a similar appearance may also be produced by thickening of the lining membrane. Transillumination is not helpful in young children, but in older ones it is, although it has greater limitations than the roentgenographic examination. It is rarely necessary in children to puncture a sinus simply to establish a diagnosis. Clouding of the ethmoid cells may be demonstrated on the roentgenogram in acute and chronic ethmoiditis. Serious complications are otitis media, meningitis, cavernous sinus thrombosis, optic neuritis, orbital cellulitis and abscess, and nephritis.

**Treatment.** Treatment is essentially that of the rhinitis. Shrinkage of the nasal mucous membranes will often facilitate drainage from the sinus. Gentle suction or aspiration may be

used, but may be more of an annoyance than a help, especially in infants. Drainage of a sinus is rarely necessary, but, if there is persistence of local and systemic manifestations, it may be justified. Appropriate antimicrobial therapy should be used in full dosage.

#### CHRONIC SINUSITIS

Chronic infection of the paranasal sinuses should always suggest the possibility of a local or generalized disturbance which facilitates persistence of the infection. Search should be made for nasal deformities and infected and hypertrophied adenoids which might cause obstruction, for infected teeth as a source of maxillary sinusitis, and for such general disturbances as allergy and nutritional and thyroid deficiencies. The incidence of sinusitis is said to be greater in children who have had their tonsils and adenoids removed.

**Clinical Manifestations.** Symptoms of chronic sinusitis vary considerably. Fever, when present, is low grade, and there is frequently malaise, easy fatigability, difficulty in mental concentration, anorexia and malnutrition. Nasal discharge, which may be bilateral or unilateral, varies from day to day, and may be greater during a certain portion of the day. Postnasal discharge or drip is common and, in the absence of infected adenoids, is practically diagnostic. Headaches are frequent, and pain or tenderness to palpation or percussion is helpful in localization. There are frequent attacks of sneezing; when there is an associated watery, nasal discharge, the possibility of allergic rhinitis must be considered.

Sinus disease should be suspected when there is persistent mouth breathing, not otherwise explained, and constant pharyngeal irritation. Any of the complications mentioned under Acute Sinusitis may occur with chronic sinusitis, but probably the most frequent one is chronic bronchial infection. The term "sinobronchitis" is used frequently to designate the relationship.

**Treatment.** Attention should be given to the general health of the child, and the diet should be corrected as necessary. Locally obstructive nasal deformities should be corrected, if possible, and infected or hypertrophic adenoid tissue should be removed. Shrinkage of the mucous membranes by ephedrine or other related compounds with the head in such a position as to facilitate entrance of the solution into the sinuses may be of some benefit. Either the so-called displacement method of Proetz or the lateral head-low posture of Parkinson may be used.

In the latter the child lies on his side with the shoulder elevated by a firm pad such as a folded blanket, and the head is bent down to a dependent position. The nasal solution which is then instilled can be expected to have contact with the various sinusal ostia on both sides. The child should breathe through the mouth to prevent drawing the medication into the pharynx. The position is maintained for five to six minutes, and the face is then turned downward for a few moments to permit drainage of the nasal contents, or the child may sit up and place the head down between the knees.

Nasopharyngeal cultures and antibiotic susceptibility tests should be obtained as a guide in selection of antibiotic agents. Such therapy should be continued for about two weeks. Continued use of nasal solutions should be discouraged.

Every effort should be made to avoid operative procedures; but when there is persistence of chronic purulent sinusitis in spite of all nonoperative measures, surgery is indicated. At times removal of the child to a warm, dry climate is beneficial.

## GENERAL CONSIDERATIONS OF CHRONIC INFECTIONS OF THE UPPER RESPIRATORY TRACT

### THE PROBLEM OF CHRONIC COLDS

One of the disturbing problems of pediatric practice is that of the child with persistent or recurring upper respiratory tract infection with or without associated chronic bronchial involvement. By no means can all children with such chronic infections be placed in the same category; rather, each must be studied to determine, if possible, the underlying factor or factors.

In general, the age of greatest incidence of respiratory infections is from the latter part of the first year of life to six or seven years. During this time it can be expected that the average child will have three to six "colds" a year. However, recovery should occur after each attack, and the child should appear healthy in the meantime. In the so-called chronic cases the child seems to recover from one acute attack, only to enter another, or there is more or less persistent rhinitis, cough and a general failure to do well. Such patterns may reflect what appears to be a familial or individual susceptibility or repeated exposure to respiratory infection within the home. Often there is some underlying disturbance in the child. Specifically included in the "chronic respiratory group" are chronic rhinitis, sinusitis, infected adenoids and tonsils,

chronic otitis media, chronic bronchitis, bronchiectasis, tuberculosis, allergy and hypogammaglobulinemia.

### CHRONIC RHINITIS

Chronic rhinitis as evidenced by a chronic nasal discharge, with or without a tendency to acute exacerbations, is usually a reflection of some particular underlying disturbance, such as infected adenoids, nasal polyps, chronic sinusitis, allergy, foreign bodies, deviated septum, various congenital malformations, nasal diphtheria, or syphilis. Chronic rhinitis should be considered merely a symptom, and the differential diagnosis should include the various disturbances enumerated. In addition, the possibility of a chronic debilitating infection or some nutritional or metabolic deficiency (as of the thyroid) must also be considered.

**Clinical Manifestations.** Symptoms vary with the individual case, but chronic nasal discharge is common to all. In the persistent cases the odor may be foul, and there may be excoriation of the anterior nares and upper lip. Bloody discharge is likely to be present in syphilitic and diphtheritic lesions and in association with foreign bodies, but may also occur in other conditions, especially if there are excoriations from persistent picking of the nose. Disturbances of taste and smell are frequent. During exacerbations or superimposed infections, fever is common, but otherwise is usually absent. Chronic sinusitis, otitis media, pharyngitis and bronchitis are frequently associated.

*Nasal polyps* are most frequently associated with allergy or sinusitis, and often produce symptoms predominantly unilateral. Their presence is determined by direct examination. They should be removed and the underlying disturbance treated (see *encephalocele*, p. 745).

Persistent *hypertrophic rhinitis* is also most often associated with chronic sinusitis or allergy. Especially in the latter condition the mucous membrane tends to be pink or pale in contrast to the usual red color. The soft tissues are swollen and resistant to pressure. Nasal obstruction may occur in a cyclic pattern.

*Atrophic rhinitis* is uncommon in children and is rare before late childhood. It is said to be more frequent in girls. It is usually associated with some general debilitating condition, or it may be a sequel to long-continued nasal infection. The sense of smell

is impaired. There may be little or no discharge, but there is likely to be considerable crusting and a sense of dryness in the nose and throat. In other instances there is a profuse, excessively foul nasal discharge (*ozena*). Direct examination shows abnormally wide nasal passages with atrophy of the mucous membrane and even of underlying structures.

**Treatment.** Treatment must be directed toward the underlying disturbance, so that each patient must be thoroughly studied. Particular emphasis must be placed upon eradicating foci of infection in sinuses, ears, adenoids or tonsils and upon the removal of all known allergens or upon desensitization to them. Attention should be given to such factors as nutritional status, rest and prevention of exposure to reinfection. In an attempt to provide symptomatic relief it is often difficult to avoid the use of such mucosal shrinking solutions as ephedrine and related compounds. It must be borne in mind, however, that their use is not without danger and they may cause further damage. There is no substantial evidence to justify the use of local antiseptics, including the silver salts and antibiotics. Systemic administration of antibacterial agents is, however, indicated in selected cases.

### CHRONIC PHARYNGITIS

Chronic pharyngitis is essentially a secondary condition resulting from such chronic infections as those of the sinuses, adenoids and tonsils, although on occasion there is no other evidence of infection than that of the hypertrophied lymphoid tissue on the posterior pharyngeal wall and on the base of the tongue. The latter type of involvement occurs with frequency only in children whose faucial tonsils have been removed, some of whom have infected tonsillar tags.

**Clinical Manifestations.** There are likely to be repeated acute exacerbations; in the intervals there are complaints of discomfort in the throat such as dryness and a raspy irritation. There are frequent efforts to clear the throat, and an irritative type of cough is common. The mucous membrane is usually inflamed, though on occasion it is pale, and the blood vessels are prominent. The pharyngeal wall is frequently covered with a mucopurulent secretion, and the lymphoid tissue is often hypertrophied and has a pebbled appearance.

**Treatment.** Treatment should be directed toward any disturbance in the sinuses, nose

(deformities), adenoids or tonsils. Attention should also be given to the general nutrition and hygiene of the child.

### TONSILS AND ADENOIDS

The term "tonsils" is used in its commonly accepted sense of indicating the two faucial tonsils; the term "adenoids," as synonymous with hypertrophy of the pharyngeal tonsil. The tonsils and adenoids are part of the lymphoid tissues which circle the pharynx and is known collectively as Waldeyer's ring. This consists of the lymphoid tissue on the base of the tongue (lingual tonsil), the two faucial tonsils, the adenoids (pharyngeal tonsil) and the lymphoid tissue on the posterior pharyngeal wall. This tissue naturally serves as a defense against infection; when its defense mechanism is overcome, it may become a site of acute or chronic infection.

The principal disturbances are infection and hypertrophy. The latter is in most instances secondary to infection. The most important factor from a medical standpoint is the decision as to their removal. Though both tonsils and adenoids are usually removed at the same operation, there are good reasons for making the decisions for tonsillectomy and adenoidectomy separately, especially in children under four or five years of age.

### NEOPLASMS OF THE TONSILS

Neoplasms of the tonsils are rare, although papilloma, lipoma, angioma, teratoma, fibroma, plasmocytoma and lymphosarcoma have been reported.

### ACUTE TONSILLITIS

Acute infections of the tonsils are considered in the same category as acute pharyngitis and are discussed on page 750; for peritonsillar abscess, see page 754.

### CHRONIC TONSILLITIS

(CHRONICALLY HYPERTROPHIC AND INFECTED TONSILS)

The "tonsil problem" is of particular concern in pediatric practice, not only because of the frequency of chronic tonsillar involvement, but also because of its distortion by physicians and laity who have been too ready to attribute all sorts of complaints and ills to tonsillar involvement and have not been sufficiently critical in recommending or asking for tonsillectomy. A more critical attitude is developing. Tonsillar disturbances are not com-

mon during infancy, but become more frequent during childhood.

**Clinical Manifestations.** These vary considerably, but the more significant ones are recurrent attacks of sore throat or a more or less persistent one, and obstruction to swallowing or breathing; the last is more often due to adenoids. There may be a sense of dryness and irritation in the throat, and the breath may be offensive, although neither of these is diagnostic. Constitutional symptoms are neither characteristic nor, as a rule, marked. Occasionally there is low grade fever, fatigue, underweight and poor appetite. One should, of course, be certain that such symptoms are not due to other disturbances.

**Indications for Tonsillectomy.** Decision for removal of tonsils should be based so far as possible on symptoms and signs related to the tonsils; tonsillectomy should not be recommended as a possible panacea for unrelated disturbances. In general, the conditions for which tonsillectomy is considered are (1) factors directly related to the tonsils, (2) disturbances in closely related structures, and (3) systemic disturbances.

*Local indications* for removal are of two types, chronic infection and marked hypertrophy. True hypertrophy is usually the result of infection, acute or chronic, but may occur independently. Many tonsils considered to be hypertrophic actually are normal in size; the misinterpretation results from failure to appreciate that tonsils are normally relatively larger during childhood than in later years. On the other hand, infection does not always produce hypertrophy, and chronically infected tonsils may be small and embedded behind the faucial pillars. In the evaluation of chronic infection, history of repeated or essentially constant sore throat is of more value than examination. There is no certain way to demonstrate by direct observation whether tonsils are harboring chronic infection. The consistency or size of the tonsil and the presence of cheesy material within the crypts are not reliable guides. Persistent hyperemia of the anterior pillars is a more reliable sign, and enlargement of the cervical lymph nodes is supporting evidence. Persistent enlargement of the node just below and slightly in front of the angle of the jaw is especially significant. In contrast to the difficulty in determining the presence of chronic infection, hypertrophy such as to obstruct swallowing or breathing is readily detectable. Such tonsils practically meet in the midline when the throat is examined without gagging

the patient. Tonsils of average size are projected toward the midline when the child is gagged and may be interpreted by the physician who is unaware of the relatively large size of the tonsil during childhood as being hypertrophic. Before tonsillectomy is recommended it should be ascertained that the hypertrophy is chronic and not the result of a recent acute infection. Tonsils can increase in size greatly during an acute infection and recede after its subsidence.

Removal of tonsils and adenoids may be recommended for persistent carriers of diphtheria bacilli (p. 418).

Among the *disturbances in adjacent tonsillar structures*, peritonsillar (and retrotonsillar) abscess is the only definite indication for tonsillectomy. Other indications are less clear cut. There are differences of opinion as to the value of tonsillectomy for sinusitis. When there are symptoms directly referable to the tonsils, as there frequently are, there is adequate justification for their removal. The physician who recommends removal before other treatment for the sinusitis is not to be condemned, but he will be wise if he does not promise relief from the sinusitis. In many instances removal of the adenoids is more likely to be indicated than is tonsillectomy. This is also true in cases of chronic otitis media and of middle ear deafness. Suppurative cervical adenitis, when the focus of infection is not traceable to structures other than the tonsils, may also be considered an indication for tonsillectomy. There is no evidence to indicate that the removal of tonsils is justified for infections in the lower respiratory tract, although such conditions are not a contraindication if there are other reasons for tonsillectomy.

No *systemic disturbance* in itself is an indication for tonsillectomy. The decision should be based on local indications in all instances. This applies to children with rheumatic fever or glomerulonephritis as well as to those with other infections in which the tonsils may be removed in a blind search for a focus of infection or as a remedy for undernutrition.

**Tonsillectomy in relation to age of the child.** Rarely it seems advisable to recommend tonsillectomy for children two or three years of age. Every attempt should be made, however, to postpone the operation. Frequently when the operation is postponed for reasons of age, the apparent need for tonsillectomy disappears within the next year or so. Actually, in the first few years of life the indica-

tions for adenoidectomy, though infrequent, are present more often than those for tonsillectomy. Neither procedure should be performed as a prophylaxis against the common cold at any age.

***Tonsillectomy in relation to season of the year.*** Formerly it was customary to postpone elective tonsillectomy until the summer months in order to avoid the secondary dangers incident to the seasons with a high rate of respiratory infection as well as to avoid absence from school. It has been shown, however, that children who have recently had a tonsillectomy are more liable to have bulbar involvement if they acquire poliomyelitis than children who have not had such an operation. Further, the introduction of effective antibacterial agents has decreased the danger of secondary bacterial infections after tonsillectomies. For these reasons, tonsillectomies have been performed electively in the winter and spring months rather than in the summer and early fall ones (the poliomyelitis season). What effect the changed epidemiologic pattern due to the Salk vaccine will have on the choice of time of operation is not yet apparent. Whatever policy is adopted, it should be recognized that no season is ideal for tonsillectomy, and that the physician should at all times be critical in his recommendation for operation.

***Tonsillectomy in relation to active infection.*** So far as possible, tonsillectomy should be postponed until two or three weeks after subsidence of an infection. This, however, is not always possible; an occasional child seems never to be free of infection in and about the tonsils. In such a case it is justifiable to perform the operation if a sulfonamide or antibiotic is administered for a day or two before and two or three days after the operation. In rheumatic fever and glomerulonephritis, tonsillectomy should also be postponed until after the acute phase has subsided. In all instances, irrespective of the evidence of active infection, penicillin and/or a sulfonamide should be administered before and after tonsillectomy in children with a history of rheumatic infection.

***Type of Operation.*** Though this is not the place to discuss operative procedures, certain generalizations are indicated. Careful removal by dissection should be carried out to ensure that all the tonsillar tissue is removed without destruction of adjacent tissues. Too frequently small amounts of tonsillar tissue are allowed to remain which later become infected and hypertrophied, or there is removal

of adjacent tissue from the lateral pharyngeal wall, from the soft palate and even at times from the uvula. Aspiration of the throat during the operation will lessen the chances of pulmonary abscess or pneumonia. Bleeding should be completely controlled, and the child should not leave the operating room until he has dry tonsillar fossae. Radiologic treatment, which causes shrinkage of the tonsils, should be recommended only when surgery is contraindicated, as in hemophilia.

***Preoperative Preparation.*** This consists in a medical history which includes questions related to recent infection, to exposure to contagious diseases and to bleeding tendencies in the patient or his family; and a thorough physical examination should include observation for loose or carious teeth, which should be removed or repaired before tonsillectomy. Bleeding and clotting times are usually obtained, but it would seem that a careful history of bleeding tendencies is apt to be a more effective screening process. The child should be told of the operation and the procedure explained, preferably by informed parents. There should be adequate preoperative sedation with one of the barbiturates and atropine. Though food is withheld for several hours before the operation, feeding should be adequate up to this time. In children who are undernourished or are readily susceptible to ketosis, the preoperative and, if needed, postoperative intravenous administration of glucose solution is indicated.

***Postoperative Care.*** This is usually not complicated. The child should be kept in bed for the remainder of the day and at rest for several more; it is wise to encourage eating and drinking as soon as the nausea from the anesthetic has disappeared. Rinsing the mouth with an alkaline solution has certain esthetic advantages. Aspirin may be prescribed when there is considerable discomfort. Avoidance of contact with infection is of the greatest importance. The membrane which forms at the operative site is at times interpreted as being diphtheritic. Fusiform bacilli (Vincent's organisms) may be cultured from it with a high degree of regularity, but this by itself is not an indication for treatment. (See Tonsillectomy in Relation to Active Infection for suggestions as to antibacterial therapy.)

***Complications.*** Complications are not particularly frequent, but postoperative hemorrhage, lung abscess, pneumonia and septicemia do occur. Hemorrhage is, of course, the most frequent one, and should be controlled

by packing or, in the case of severe bleeding, by ligation. Extensive bleeding will be responsible for severe anemia, leukocytosis, fever, and even dilatation of the heart. Transfusion is indicated in such cases.

**Results to Be Expected from Tonsillectomy.** No reduction in the incidence of epidemic respiratory infections is to be expected. The incidence of persistent throat infections may be decreased. Obstructive symptoms due to hypertrophied tonsils can be relieved. Otitis media and sinusitis are rarely benefited by tonsillectomy; the incidence of sinusitis may even be increased. Nasal allergy is not affected, nor is the incidence of laryngitis. Pulmonary infections are not decreased, and may even be increased. The incidence of initial attacks of rheumatic fever appears to be somewhat decreased, but recurrences are not affected. The incidence of diphtheria is less in tonsillectomized children, and the carrier state may be controlled by the operation. The incidence of cervical lymphadenitis is decreased. In some instances nutrition is improved after tonsillectomy. In part this may be due to psychologic factors, but it is reasonable that general benefit should accrue when a focus of infection is removed. Care should be taken, however, in making predictions in this respect.

Follow-up studies of tonsillectomized and nontonsillectomized children for whom the operation had been recommended do not reveal striking differences in favor of the tonsillectomized group. In one large group surveyed by Dey, which consisted of children for whom tonsillectomy and/or adenoidectomy had been recommended and then deferred for at least eighteen months, it was concluded that there was no longer a need for the recommended operation in more than one third of the children.

## ADENOIDS

### (HYPERTROPHY OF THE PHARYNGEAL TONSIL)

Disturbances of the lymphoid tissue of the nasopharynx (adenoids) tend to parallel those of the faucial tonsils. Hypertrophy and infection may occur separately, but usually occur together, infection, as a rule, being primary. The soft adenoid structure, which is normally widespread in the nasopharynx, especially on the posterior wall and the roof, undergoes hypertrophy, and masses of varying size, reaching even that of a walnut, are formed. These masses may almost fill the

vault of the nasopharynx and interfere with the passage of air through the nose and obstruct the eustachian tubes.

**Clinical Manifestations.** Mouth-breathing and more or less persistent rhinitis are the most characteristic symptoms. Mouth-breathing may be present only during sleep, especially when the child is on his back, and in this position snoring is also likely to occur. In decided adenoid hypertrophy the mouth is kept open during the day as well, the mucous membranes of the mouth and lips are dry, and the child's facial expression is dull or stupid. Alteration in the shape of the nose is common, the nostrils being small and narrow, although sometimes the upper portion of the nose appears unduly broad. Chronic nasopharyngitis may be constantly present or recurs frequently. The voice is altered, developing a nasal, muffled quality. The breath is offensive, and taste and smell are impaired. A harassing cough may be present, especially at night, resulting from irritation of the larynx by inspired air which has not been properly warmed and moistened by passage through the nose. Deafness is common and may become permanent unless the obstruction of the eustachian tube has been relieved before chronic changes occur in the middle ear, which may be the seat of pyogenic infection. Chronic otitis media, with persistent or recurrent purulent drainage, may be associated with infected, hypertrophied adenoids.

Permanent bony deformities have been attributed to faulty nasal breathing, but are probably more likely the result of other factors. These deformities include a high and narrow arching of the palate, a forward projection of the upper jaw, prominent eyes, and a keel-shaped chest with lateral depression of the lower portion of the thorax.

Stunting of growth, anemia and other general effects have been attributed to adenoid hypertrophy, but in most instances are probably due to other causes. The facial expression may, as stated, be stupid, but there is no direct effect of adenoid hypertrophy on mental development except that related to deficient hearing. It would not appear that adenoid hypertrophy has any etiologic connection with such conditions as stammering, enuresis, or grinding of the teeth.

The *diagnosis* can be confirmed by direct digital palpation, examination of the vault of the pharynx by pharyngeal mirror, or roentgenographic examination. Otherwise the presence of adenoid hypertrophy can be suspected from such symptoms as mouth-breathing.

snoring and persistent rhinitis with or without chronic otitis media.

**Suppurative Adenoiditis.** A recent description by Goldbloom (original source, Libman) of an abscess in the adenoid tissue as a cause of protracted fever is of interest. The characteristic clinical pattern described is as follows: throat infection of several days' duration four to six weeks previously is followed after a few symptom-free days by resumption of the fever with daily temperatures to 102° F. or higher. The lymph nodes under the sternocleidomastoid may or may not be enlarged. The child usually has no symptoms, including none of the nasopharynx, but occasionally may complain of headache, often occipital in location. The white blood cell count is indicative of a purulent infection. The clinical course is terminated by expressing pus from the enlarged boggy adenoids with the finger. Subsequently, adenoidectomy is advised.

**Treatment.** Surgical removal is indicated when there are symptoms such as persistent mouth-breathing, "nasal" speech, repeated attacks of otitis media, deafness and persistent or recurring nasopharyngitis. Improvement occasionally results from change in climate or with appropriate antibiotic treatment administered for ten to fourteen days; operation can then be deferred, especially in young infants. It is customary to remove the adenoids when tonsillectomy is performed, although there are occasions, particularly in young children, when only adenoidectomy should be recommended. The same precautions for complete removal and control of bleeding points as recommended for tonsillectomy should be observed; for this reason, removal under direct vision is preferable to the use of the adenotome. If impaired hearing persists after adenoidectomy, radiation therapy may be considered.

# THE EAR

## MALFORMATIONS

The majority of malformations of the ear are congenital in origin. They include abnormalities of the auricle, external auditory canal, middle ear and inner ear. The abnormalities of the auricle are varied, owing to its complex embryologic development; they include aplasia, hypertrophy, partial development, and variations in size and shape. Aplasia of the auricle may be partial or complete. The external auditory canal may be present, though covered by the deformed auricle, but more often abnormalities of the external auditory canal, tympanic membrane, middle and inner ear accompany the congenitally deformed auricle. There may be absence or fusion of the ossicles.

In the female child with a unilateral auricular deformity nothing need be done; when there are bilateral deformities, correction to improve hearing is a necessity. In the male child operations to improve both function and appearance are indicated.

Instead of attempting to reproduce a new external auditory canal, the auricle is mobilized, and the mastoid excavated and lined with skin grafts. The auricle is shifted over the mastoid cavity, which serves as the new canal. Additional hearing improvement is obtained by fenestrating the external auditory canal. After the hearing has improved, a new auricle may be constructed. At times prosthetic devices are used, an auricle of plastic material being held in place with adhesive.

Congenital outstanding ears, or lop ears, are often a source of great embarrassment. Correction should be done before the child starts school. Restraining devices are of little benefit, since the anomaly is due to absence of the antihelix fold. The operation is usually effective.

Small preauricular fistulas, which are remnants of the first branchial cleft, are common and often extend into the temporomandibular joint. If they become infected, there is liable to be persistent purulent drainage, and surgical resection is indicated. To secure a successful result, the entire fistulous tract must be dissected and removed. Methylene blue is injected into the tract, and dissection is carried to its depth.

A traumatic lesion of the auricle may re-

sult in a hematoma and in deformity if untreated. The hematoma should be evacuated immediately by aspiration or incision, and a tight bandage applied to prevent further infiltration, fibrosis and ultimately a "cauliflower ear." *Abscess of the auricle*, secondary to perichondritis or chondritis, can usually be treated adequately by antibiotic therapy. If fluctuation occurs, prompt incision and drainage are indicated.

## FOREIGN BODIES

Various animate or inanimate foreign bodies may be introduced into the external auditory canal. Unless they are visible, within easy reach, and the child is cooperative, it is best to remove the object under general anesthesia. Irrigation of organic particles should be avoided, since absorption of water may increase their size. Occasionally, if the foreign body is tightly impacted, a postauricular incision may be needed for removal.

Cerumen may become inspissated and impacted. A small mass of cerumen may be removed by gentle and careful extraction with a hook or curette. Large masses should be softened with oil or a detergent soap solution and then removed by irrigation with warm water. A 20-cc. glass syringe to which is attached a piece of a no. 8 French soft rubber catheter makes a good irrigating apparatus and will avoid injury.\*

## OTITIS EXTERNA

Otitis externa may occur at any age. It may follow trauma or swimming in contaminated waters. Sometimes it is due to mechanical probing in an attempt to clean the external auditory canal, a procedure which is rarely necessary and should never be performed by an inexperienced person.

*Symptoms* are pain, redness and swelling of the external canal and auricle and at times of the postauricular area. There is pain on motion of the auricle and on pressure over

\* The deVilbiss Company makes an excellent irrigating device which is operated by compressed air; it provides a steady stream of water without the necessity of filling a syringe or pushing a plunger, thus avoiding trauma to the canal in an uncooperative child.

the tragus. The temperature may be elevated if the cellulitis is diffuse.

*Treatment* consists of hot packs of Bur-ow's solution and broad-spectrum antibiotic coverage, systemically and locally (ear wick). The infection is frequently ascribed to a fungus, but it is usually bacterial in origin, often being caused by *Pseudomonas* organisms. Resolution usually occurs, and incision and drainage are seldom necessary.

*Vesiculation* of the auditory canal may be due to viral infection such as that of herpes simplex or influenza. This infection may be accompanied by severe pain in the canal and over the mastoid area and by fever. The so-called *Ramsay Hunt syndrome* is a herpes zoster infection of the geniculate ganglion, with dermal lesions of the auricular region, at times with a facial paralysis.

Hemorrhagic blebs may fill the ear canal and cover the tympanic membrane in viral infections, especially influenzal ones. Relief may be obtained by rupturing the blebs with a cotton-tipped applicator.

## THE TYMPANIC MEMBRANE

The normal drum is gray and translucent, the short process of the malleus, the umbo and the cone of light being easily visible.

Diseases of the tympanic membrane include otitis externa, otitis externa hemorrhagica bullosa and herpes zoster oticus. In the early stages of otitis media the drum membrane is red and injected (acute myringitis). The appearance of the drum head usually reflects the inflammatory processes within the middle ear.

Perforations of the ear drum occur as the result of trauma as well as of infection of the middle ear. Trauma is most often indirect, such as a blow with the open palm over the auricle, severe head injuries and concussion from an explosion.

The perforation is followed immediately by bleeding, pain and hearing impairment. Otoscopic examination reveals the extent of the damage. The canal should be kept closed with sterile cotton, and an antibiotic should be administered to prevent infection. No liquid (drops) should be put in the canal. The perforation will often heal spontaneously, but healing may be hastened by touching its edges with trichloroacetic acid or silver nitrate, or freshening them with a myringotomy knife. The perforation may be covered with cellophane or Cargile membrane, which may act as a bridge for epithelization.

## OTITIS MEDIA

### ACUTE OTITIS MEDIA

Acute otitis media is usually secondary to an upper respiratory infection, especially a nasopharyngitis, and is often a sequel of measles or scarlet fever. The incidence is greater in the young infant, supposedly because the eustachian tube is shorter and wider, and because the infant is supine most of the time. Actually, infection may spread through the subepithelial pathways and lymphatics from the nasal mucosa or by direct extension from the nasopharyngeal area. The first stage is due to closure of the eustachian tube, which is followed by congestion, serous exudation and infection.

In the untreated case the *symptoms* are pain in the ear, which increases in intensity as exudation occurs, and an elevated temperature. The young infant may cry fretfully and rub the affected ear. The pain becomes intense as the fluid pressure of the middle ear increases. Occasionally there may be nausea and vomiting and signs of meningeal irritation. Inspection of the tympanic membrane reveals a red and congested ear drum with loss of the normal landmarks in the early stage; later there may be edema and bulging of the membrane.

**Clinical Course and Treatment.** In untreated cases the temperature and pain may persist until spontaneous rupture occurs. If the drum is red and congested, but the normal landmarks are still visible and there is little fullness, appropriate antibacterial therapy will usually result in resolution. Nasal treatments should also be carried out, when indicated. If, after therapy for forty-eight hours, there are no signs of resolution and the appearance of the drum suggests the presence of fluid, myringotomy under local or general anesthesia or aspiration of the middle ear (as described under Serous Otitis Media) should be performed. If bulging is present at the first examination, myringotomy should be performed immediately and antibacterial therapy started. A culture should be made from the myringotomy knife, and antibiotic sensitivity tests obtained for any pathogenic organism isolated, as a further guide to therapy. No harm will result from a well performed myringotomy, but delay or failure to perform it may result in an attenuated (chronic) infection, impaired hearing or an acute exacerbation when the antibiotic is discontinued.

FIG. 212. Aspiration of middle ear for treatment of serous otitis media. A and B, Application of topical anesthesia; the pack is allowed to remain *against* the drum for 10 to 15 minutes. C, After the fine needle has perforated the anterior-inferior quadrant of the drum mild suction is applied. Note the aspirated fluid in the tube. The device illustrated is the Gottschalk apparatus; it can also be used with oral suction.

FIG. 213. Audiometric studies of a patient with serous otitis media. 1, Unbroken lines indicate hearing loss before treatment, which consisted of needle aspiration and systemic administration of antihistaminic and antibiotic drugs. The second audiogram (2, broken lines) shows the immediate improvement in hearing after aspiration of the serous fluid.

Antibacterial therapy should always be given in full dosage and for a sufficient time to ensure complete resolution.

Complications are rare and are usually the result of inadequate (suppressive) therapy. They include acute mastoiditis, chronic otitis media, chronic mastoiditis, lateral sinus thrombophlebitis or thrombosis, septicemia, meningitis, cerebral or cerebellar abscess, labyrinthitis, petrositis and facial paralysis.

#### SEROUS OTITIS MEDIA

Serous otitis media is a condition in which fluid is present in the middle ear. The fluid

may be clear, mucoid or purulent. The etiology may be on an allergic basis, or the cause may be a partially attenuated middle ear infection.

The child complains of a fullness in the middle ear and impaired hearing. There is usually no real pain or fever, but there may be a sensation of something moving about in the ear. Otoscopic examination reveals a gray membrane, which at first glance seems normal, but on closer inspection the drum is opaque, a yellowish reflex is present, and there is some fullness. On occasion a fluid level may be seen. The audiometric test re-

veals an obstructive type of deafness. The diagnosis is confirmed by the aspiration of fluid (Fig. 212), which also relieves the symptoms; the hearing is improved immediately.

*Treatment* consists in repeated aspirations with a fine needle. If the child is uncooperative, a myringotomy with suction aspiration should be performed under general anesthesia. Local anesthesia may be obtained by placing a piece of cotton saturated with a solution of cocaine and aniline, U.S.P. (10 to 90 parts, respectively), against the drum. When the fluid is very viscid, a myringotomy followed by aspiration with a fine suction tip is required. Subsequently any existing allergic or infectious condition should be treated appropriately. When hypertrophied adenoid tissue is a factor, its removal may be indicated; if an adenoidectomy has previously been performed, radiation therapy may be considered. Such therapy is not without danger and should be used advisedly and only by an experienced person. Inflation of the middle ear by the Polit-

zer technique may aid in hastening resolution.

### CHRONIC OTITIS MEDIA

Chronic otitis media is now relatively rare, owing to the effectiveness of antibacterial agents for the prevention and treatment of acute otitis media. When a middle ear infection persists for three to six weeks after adequate drainage and antibacterial therapy, a roentgenogram of the mastoid should be obtained. When there is evidence of mastoiditis, a "complete mastoidectomy" is indicated. It should result in resolution of the middle ear infection and prevent chronic otitis media and deafness.

Chronic otitis media accompanied by perforation of the drum in Shrapnell's region and by clinical and roentgenographic evidence of cholesteatoma should be treated by a so-called mastoido-atticotomy or Bondy operation, which may be accomplished postauricularly or endaurally. It should result in a dry ear with preservation of the tympanic membrane and ossicles as well as hearing.

## DISTURBANCES OF THE INNER EAR, MENINGES, LATERAL SINUS AND FACIAL NERVE

Chronic tuberculous otitis media and mastoiditis should be treated by mastoidectomy and intensive antibacterial therapy.

*Labyrinthitis* may be secondary to acute or chronic otitis media and/or mastoiditis. Acute purulent labyrinthitis is accompanied by signs of meningeal irritation, nystagmus, deafness, nausea and vomiting. Spinal puncture reveals an increased number of cells. There is usually evidence of mastoiditis. The treatment of choice is mastoidectomy with appropriate antibacterial therapy. Severe or complete deafness in childhood may be the result of unrecognized labyrinthitis, which may be due to inadequate antibiotic therapy. Though the clinical manifestations are suppressed, the disease progresses, and total deafness occurs. Ménière's labyrinthitis of allergic origin may occur in childhood, as may toxic labyrinthitis involving the vestibular or cochlear portion of the endolabyrinth, during viral infections, especially mumps, and bacterial infections.

Deafness and loss of the vestibular function of equilibrium are the most serious of the toxic reactions to streptomycin.

*Otitic meningitis* is now relatively uncommon. When it occurs, removal of the suppurative focus in the middle ear and mastoid

must be prompt and complete; otherwise antibacterial therapy is likely to be ineffective.

*Phlebitis or thrombosis of the lateral sinus* is now a rare complication of otitic infections. The characteristic symptoms are likely to be modified or masked by the antibacterial therapy being administered. There may be no directly referable symptoms, the only evidence being that of a persistent infection. The classic pattern includes chills, a high septic type of fever, a positive blood culture, a positive Ayer-Tobey test and thrombotic phenomena.

*Facial paralysis* occurring early in the course of acute otitis media is usually toxic in origin and will disappear with proper treatment of the middle ear infection. When the paralysis occurs late in the course of an otitis media, it may indicate a mastoiditis, and a mastoidectomy is necessary.

### MASTOIDITIS

The incidence of purulent mastoiditis has been reduced by antibacterial treatment of acute otitis media so that it is now relatively rare. When "surgical" mastoiditis does occur, it is usually because the child has had no

or inadequate antibacterial therapy or because there has been inadequate drainage of the middle ear infection. The symptoms include postauricular pain, fever, fullness of the ear drum, occasional edema of the postsuperior portion of the external auditory canal and roentgenographic evidence of mastoiditis.

In rare instances, when there is pneumatization and cellular formation of the zygomatic process of the temporal bone, an infection in the mastoid may extend to involve these cells. The osseous and soft tissue involvement may result in swelling and inflammation over the temporo-mandibular region.

## IMPAIRED HEARING

Impaired hearing is a complex problem and requires well planned and coordinated teamwork for its solution. This team includes the child, his family, the child's physician, the otologist, the audiologist, the speech therapist and often the psychologist and/or psychiatrist. There is little value in discovering hearing losses unless something is done about them.

### CONGENITAL DEAFNESS

Congenital deafness may be complete or partial; it may be due to a lack of development, or to disease, in the organ of Corti. Although the entire labyrinth may be involved, usually the vestibular apparatus retains normal function.

It is difficult to detect hearing loss accurately in infants. The deaf infant at two or three months of age coos with pleasure or cries with pain just as a hearing one does, but when the hearing infant reaches the age of six or seven months, he usually begins to respond to the sounds made by others, whereas the deaf infant does not. At twelve to sixteen months of age the noises made by

the hearing child begin to be recognizable as words, but the deaf child by this age may have almost ceased to vocalize. Conditioned psychogalvanic skin reaction tests may give some information as to presence or absence of hearing. The auropalpebral reflex or other reflex reactions to sound elicited by striking a C-4 or C-5 tuning fork or other type of noisemaker near the side of the head may give useful information about the hearing. Noisemakers such as whistles, drums or bells may be calibrated in terms of the sound pressure levels they produce. Such relatively crude hearing tests often are of considerable diagnostic value. A determination of the degree of deafness in infants and young children may necessitate a series of examinations.

A child of eighteen months who makes no attempt at verbal response must be suspected of being deaf. Because it is often difficult for parents to believe that the random noises the child is making are not attempts at speech, but merely reflexive movements of the oral mechanism, the child may be three or four years of age before he is taken to a physician for diagnostic appraisal. A child with impaired hearing who is deprived of any means of communication may become physically aggressive and in many respects almost unmanageable.

In contrast to their lack of auditory ability, these children may be otherwise alert. They learn the performance of various physical means of expression quickly, and often are remarkably dexterous. They become highly conditioned to family routine, and develop spontaneously the ability to read the lips of their parents so accurately that parents are convinced they can hear.

A child with a serious hearing impairment does not learn speech in the usual way. He must be taught by special methods to utilize any hearing he may have and to make use of his visual and kinesthetic senses in acquiring speech. This training can best be started when the child is two and one-half to three years of age, at a time when the normally hearing child is learning to talk. These early hearing losses usually are not progressive, nor do they respond to any known form of medical treatment. It is important that physicians inform parents that the congenitally deaf child can achieve a satisfactory means of communication. Special instruction is available for the parents as well as for the children.

## ACQUIRED DEAFNESS

The problem is quite different when the child has developed speech and then acquired a hearing loss, even a severe one. He has developed a cortical speech pattern which, under favorable circumstances, can be kept alive. The muscles involved in speech have attained a certain degree of development, and the child has known the rhythm and physical sensation of vocalized sounds.

Since some residual hearing is present in most cases, these children can benefit by auditory training with the assistance of electronic amplification. They can also profit from lip-reading instruction, speech training and psychological guidance. Acquired deafness may be caused by middle ear infections and their sequels and also by toxic effects of infectious diseases and of certain drugs upon the inner ear and/or the eighth cranial nerve. Severe and permanent deafness may follow meningitis, encephalitis, scarlet fever, measles, typhoid fever, influenza, mumps, and the like. Streptomycin is an example of a drug with high toxicity; it affects mainly the vestibular function, whereas dihydrostreptomycin tends to impair the cochlear function. Middle ear infections are usually amenable to treatment, so that an impairment can be avoided or at least can be ameliorated in a high percentage of cases. However, there is no known cure for cochlear or eighth nerve degeneration following any of the infectious diseases named above.

## DETECTION OF HEARING IMPAIRMENT

The prime requisite is early diagnosis, irrespective of age or cause. But mere demonstration of hearing loss is not sufficient; its extent and nature must also be established.

**In the Preschool Child.** Techniques for the quantitative measurement of the auditory acuity of preschool children leave much to be desired, because the child's cooperation is essential. It is usually necessary for the child to have sufficient speech and language development to understand the instructions for the test and to have some capacity for attention and concentration. In the evaluation of any child whose speech development is delayed or who develops unintelligible speech, the possibility of a hearing loss must be considered until an accurate quantitative evaluation of his hearing can be obtained.

If the child is unable to repeat simple words or sentences at various intensity levels

or to respond to the tones produced by a pure-tone audiometer, it is customary to observe his reactions when noises of graduated intensity are produced near him, but out of his range of vision. Calling his name, clapping the hands, blowing a police or referee's whistle and striking a Koenig rod are noises used for testing purposes. Noises of exceedingly high intensity levels stimulate the threshold of feeling to which children with total loss of hearing respond. If a child shows no reaction to any of the sounds mentioned, his response to floor vibration when an object is dropped behind him will indicate that he probably has a hearing impairment.

Dix and Hallpike devised a hearing test by means of which preschool children can be conditioned to respond to pure tones of different intensity levels, and Ewing and Ewing described several tests based on observation of the child's behavior or response during play periods. Keaster developed a quantitative test which indicates the intensity levels at which the child can identify simple pictures; it can be used only for children who have sufficient speech to indicate that they recognize the objects.

**In the School-Age Child.** It is possible to obtain accurate quantitative measurements of the auditory acuity of children five years of age and older with pure-tone and speech audiometers. The tuning fork, watch tick, coin click and direct whispered or spoken voice tests, as usually administered, are grossly inaccurate as compared to the audiometer tests.

The pure-tone audiometer measures the acuity in calibrated steps of frequency (pitch) and intensity (loudness). Frequencywise, test signals are provided in octave and/or semi-octave intervals within a range of 64 to 12,000 cycles per second (cps). Intensitywise, steps are provided in intervals of 5 decibels (db), since steps of that magnitude are easily recognized even by persons unfamiliar with audiometric tests. Since the decibel is a relative measure, absolute calibration of intensity is achieved in the following manner. Zero decibel represents the intensity level at which a given tone is barely perceived by young adults (persons under thirty years of age) with normal hearing acuity in quiet rooms. (Normal hearing in this respect has a range of plus or minus 5 decibels around the mean value.) This threshold intensity level differs from frequency to frequency, the ear being most sensitive within the range of 3000 to 4000 cycles per second. The intensity range

of audiometers, in terms of hearing loss, extends from -10 (better than normal) to approximately 100 decibels, the latter value varying somewhat with frequency.

This method of calibration permits measuring hearing losses for any frequency in terms of the decibel ratio in relation to the normal threshold value. For reasons of convenience the zero decibel level is plotted as a straight line near the top of the audiogram blank. The audiometer and the audiogram blank now make available, respectively, a standardized instrument for the testing of hearing and a standardized method of recording the results of hearing tests.

**Interpretation of Audiograms.** Criteria which can be used in the localization of pathologic changes within the ear are the severity of the hearing impairment at different frequency levels, the relationship between air and bone conduction acuity, and the ability to understand speech above threshold intensity levels. As a rule, patients with involvement of the inner ear have greater losses in acuity for high frequency tones than for low frequency ones, and those with involvement of the middle ear have equal losses for all tones over the audiometric frequency range. Patients with involvement only of the middle ear never have a complete loss of hearing, usually not exceeding 60 decibels. It is about at this latter value that vibrations which sound sets up in the entire skull are transmitted to the inner ear, even when the middle ear pathway is entirely blocked, for example by an atresia of the external auditory canal. Patients with lesions of the inner ear may have any degree of impairment, including total loss of auditory function.

The relationship between air and bone conduction acuity in different types of hearing impairment can be summarized as follows: (1) When there is a hearing deficit by air conduction and none by bone conduction, the lesion is in the middle ear. (2) When the patient has an equal loss for both air- and bone-conducted sound, or possibly a slightly greater loss for bone conduction, the involvement is in the inner ear (usually the history and physical examination contraindicate middle ear involvement in these cases). (3) When there are losses for both air and bone conduction, but a greater loss for air conduction, there is involvement of both the middle and inner portions of the ear.

A further means of differentiation is provided by the so-called recruitment phenomenon: this is the sensation of loudness which

increases at a rate faster than normal when the intensity of the test signal is raised. Recruitment is displayed by persons with inner ear involvement, whereas in persons of middle ear involvement the rate of increase of loudness follows the pattern of normal ears. Pure-tone audiograms alone do not provide adequate clues for differentiation of lesions of the inner ear from those of central origin. Here examination of the patient's ability to synthesize sounds above threshold, e.g., in the perception of speech signals, has proved helpful. Walsh and Silverman and also Davis described the differences in reception of speech above threshold levels by the impaired ear. Briefly, the reception of speech by persons with disease of the middle ear increases to the normal or near-normal value if the intensity of the speech is increased sufficiently. By contrast, in persons with disease of the inner ear the intelligibility of speech does not increase to the same extent no matter how high the intensity level is raised. This failure of synthesizing speech is especially marked in central disturbances of the auditory function. The term "phonemic regression" is used to describe this condition, which is conspicuous in that a given loss of hearing for pure tones is associated with a relatively severe loss for speech perception. As a further means of differentiation, there is no recruitment in hearing losses of central origin.

From the foregoing, it is evident that persons with middle ear involvement benefit maximally from sound amplification provided by hearing aids, whereas persons with inner ear or central types of hearing losses obtain only limited help from these devices. If a hearing loss exceeds about 30 decibels, a person is socially handicapped as far as his verbal communication ability is concerned. A person with approximately 80 decibels hearing loss has a complete loss of serviceable hearing for speech, and usually receives limited help from the use of hearing aids.

**Labyrinthine Examination.** All children with a hearing loss should have an examination of the static labyrinth. Vastine said: "As goeth the labyrinth, so goes the cochlea." The reverse could also hold true. Caloric and turning tests as well as nerve electrical stimulation tests of vestibular function should be carried out whenever possible.

#### CONSERVATION-OF-HEARING PROGRAMS

Effective treatment of hearing impairment is dependent upon early detection. The two most important methods of detection are

routine testing of the hearing of school children and of preschool children as a part of their regular health examinations. School children should all be examined at least every three years; those who are known to have borderline hearing impairment, speech defects or acquired ear trouble should be examined promptly.

A complete hearing clinic requires the services of otologists, audiologists, speech pathologists, pediatricians, psychologists, psychiatrists, special education experts and social workers to evaluate and assist the hard-of-hearing child. A number of such clinics have been established by educational institutions and foundations.

Hearing-testing programs for school children should be sponsored by each state and should have the support and cooperation of the state and county medical societies as well as the local school authorities. Each county medical society should appoint an otologist to examine children found to have definite hearing losses. Parents should be present during these examinations and, if treatment and further examinations are necessary, should be advised to take their children to private otologists or clinics. The school nurse or some other staff member should follow through on each case to see that the children with hearing impairment secure proper treatment.

All children with speech defects which appear to be due to a hearing loss and those whose better ear has an impairment of 25 decibels or more at 500, 1000 or 2000 cycles, which does not improve with medical care within six months, should be referred for speech training and lip reading. Hearing aids should be considered for children whose hearing shows an impairment of 30 decibels or more at 500, 1000 or 2000 cycles and does not improve within six months with medical care. Children with average intelligence quotients who fail repeatedly in their schoolwork because of impaired hearing, in spite of assistance of medical treatment, lip reading and hearing aids, should be referred to a school for the deaf.

Prevention of hearing losses is of first importance. Preventive methods include (1) immunization of children against contagious diseases which may endanger hearing; (2) avoidance of swimming by children with dry perforations of the ear drum and by all children during acute upper respiratory tract infections; (3) appropriate management of acute upper respiratory tract infections; and (4) prompt and adequate treatment of purulent

otitis media. Additional measures which may be of value in preventing hearing losses are the removal of wax in the external canal, prompt treatment of external otitis, removal of infected lymphoid tissue in the nasopharynx, treatment of sinus infections, control of allergy, treatment of metabolic disorders and avoidance of drugs which damage the eighth nerve.

Serous otitis media is common, especially among smaller children, and in this age of the antibiotics often considered harmless. Although antibiotic treatment will prevent complications, such as purulent otitis media and mastoiditis, it frequently fails to resolve the infection, which continues at a low, sub-clinical level. Eventually the exudate is organized, scar tissue is formed in the middle ear, and function is permanently impaired. This sequence of events makes it imperative to drain accumulations of fluid of the middle ear through myringotomy, repeatedly if necessary, and to apply suction in order to remove the tenacious secretions (see p. 765).

Careful audiometry is essential not only for the diagnosis of hearing loss, but also for evaluation and guidance of therapy. It is entirely improper to continue therapy of any kind unless measurable improvement is manifested by repeated audiometric measurements.

Every child with a permanent or irreversible hearing loss should be evaluated from many aspects in relation to his educational, economic and social future. His speech de-

velopment, intelligence, school achievement, personality adjustment and his parents' understanding of his problems must be known and evaluated.

## THE LARYNX

Symptoms referable to disturbances of the larynx are dyspnea, stridor, wheezing, hoarseness and aphonia. Dyspnea may be due to other causes, but the dyspnea of laryngeal obstruction is characteristically associated with inspiratory indrawing at the suprasternal notch and supraclavicular spaces, as well as with stridor. However, not all inspiratory indrawing at the suprasternal notch is the result of high obstruction; it also occurs when the accessory muscles of respiration are brought into play as in generalized obstructive emphysema (see p. 806). Wheezing of laryngeal disease occurs in the inspiratory phase in contrast to that of asthma and other bronchiolitic disturbances, which is predominantly in the expiratory phase.

The only method of examining the larynx

FIG. 214. Direct laryngoscopy affords the only means of objective examination of the larynx in an infant or a child under 6 years of age.

of a child under six or seven years of age is by direct laryngoscopy (Fig. 214). Direct laryngoscopic examination is therefore indicated in the presence of the symptoms mentioned and may afford a means of treatment as well as of diagnosis. Thorough physical examination, appropriate roentgenographic examination and bacteriologic studies are also essential for the appraisal of laryngeal disease.

## CONGENITAL MALFORMATIONS

### CONGENITAL LARYNGEAL STRIDOR

Noisy, crowing respiratory sounds, usually associated with inspiration, are relatively common in the neonatal period and during the first year of life. Some infants merely have noisy breathing, whereas others have a laryngeal "crow," hoarseness or aphonia, dyspnea, and inspiratory retractions in the supraclavicular, intercostal and subcostal spaces. If inspiratory retractions are severe, deformity of the thorax may result. Infants with severe dyspnea frequently have difficulty in nursing, so that undernutrition is common. Cyanosis is rarely observed. Respiratory infections tend to exaggerate all the symptoms.

In the first few days of life it may be difficult to distinguish between congenital disturbances of the larynx and transient disturbances such as the laryngospasm of tetany of the newborn or laryngeal edema secondary to trauma or aspiration of irritant substances at birth. The history of aspiration at birth, hoarseness or aphonia and laryngoscopic examination establish the presence of post-natal laryngeal edema.

Stridor persisting or appearing after the first few days of life usually results from disturbances in or adjacent to the larynx. The most common of these is congenital deformity or flabbiness of the epiglottis and supraglottic aperture. Developmental malformations may be present, or there may merely be an exaggeration of the normal "omega" shape of the infantile epiglottis. Anomalies of the larynx

include malformations of the laryngeal cartilages, intraluminal webs, and malformations or duplication of the vocal cords. At times generalized chondromalacia of the larynx and trachea may be observed. In such instances the larynx and trachea tend to collapse with inspiration and to expand with expiration. Congenital tumors such as fibromas of the larynx are rare. Mucous retention cysts, branchial cleft cysts and thyroglossal duct remnants are other infrequent causes of stridor. Birth trauma must also be considered in the differential diagnosis.

Stridor may also be produced by extralaryngeal causes. Hypoplasia of the mandible permits the base of the tongue to interfere with the epiglottis. Macroglossia from hypertrophy of the muscles, hemangioma, lymphangioma or cysts may have the same effect. Compression of the larynx by congenital goiters has been reported. Congenital vascular anomalies (p. 877) may also cause stridor. Enlargement of the thymus is rarely, if ever, responsible for stridor.

**Diagnosis.** Most cases of congenital laryngeal stridor can be diagnosed only by direct laryngoscopy. Abnormalities of the epiglottis, the vocal cords and the larynx can be visualized by this examination.

Extralaryngeal causes of stridor can often be diagnosed without the aid of direct laryngoscopy. The stridor associated with macroglossia or hypoplasia of the mandible can be relieved by pulling the tongue and mandible forward. Vascular anomalies which partially occlude the trachea and esophagus can often be detected by fluoroscopic observation during a "barium swallow" (p. 877).

**Treatment.** The most common cause of laryngeal stridor, "flabby" epiglottis, rarely requires treatment. The condition is seldom serious, and symptoms gradually become less severe, generally disappearing by about one year of age. Cysts, webs, tumors and malformations of the larynx require various specialized procedures, such as excision, dilata-

FIG. 215. 1, Epiglottis of child as seen by direct laryngoscopy in the recumbent position. 2, Normal larynx spasmodically closed, as is usual on first exposure without anesthesia. 3, Same on inspiration. 4, Supraglottic papillomas as seen on direct laryngoscopy in a child of 2 years. 5, Cyst of the larynx in a child of 4 years, seen on direct laryngoscopy without anesthesia.

tion, laryngoplasty or tracheotomy. The treatment of the various extralaryngeal causes of stridor is discussed elsewhere with the descriptions of the various clinical entities.

Particular attention must be given to the feeding of infants with stridor. Aspiration is an ever-present danger. Moreover, the respiratory efforts preclude normal sucking and swallowing in some infants. Slow, careful feedings from a small nipple or by dropper or glass are usually adequate. Feeding by gavage or even gastrostomy is occasionally necessary.

Infants with stridor must be protected from respiratory infections.

### CONGENITAL WEB

This condition is not common, but its immediate diagnosis is essential. If the web is complete or almost complete, the newborn infant will quickly become asphyxiated. A few cases are on record in which such a web was perforated or removed with sufficient promptness to save the infant's life. Often the web is only sufficiently obstructive to cause stridor and mild dyspnea.

**Diagnosis and Treatment.** Direct laryngoscopy affords the means for both diagnosis and treatment. In some instances it may be necessary to insert a tracheotomy tube while a series of dilatations is carried out. If the web is incised instead of dilated, care should be taken to incise it along one cord, and subsequently to prevent the cut edges from growing together.

## TRAUMA OF THE LARYNX

### BIRTH TRAUMA

Injury of the larynx during birth is not infrequent. It may result in *dislocation of the cricothyroid or cricoarytenoid articulations*. Such an injury will result in hoarseness and at times in wheezing or fluttering respiratory sounds. The *diagnosis* is made by direct laryngoscopic examination. *Treatment* by direct laryngoscopic manipulations, using a laryngeal dilator, may be effectual, but tracheotomy should be done when there is evidence that the infant is not getting enough air.

*Unilateral or bilateral recurrent laryngeal paralysis* may also be produced by birth trauma, especially during instrumental delivery. When only one cord is paralyzed, there may be only hoarseness and a slight stridor. There is usually no dyspnea. In bilateral paralysis there is dyspnea and stridor. Direct laryngoscopic examination will establish the

diagnosis. When there is bilateral paralysis, tracheotomy is usually necessary. A valvular cannula may be worn, and later a laryngoplasty may be done to permit decannulation, unless breathing through the larynx has improved spontaneously.

### POSTNATAL TRAUMA

Any trauma such as that brought about by a fall against a hard object may produce acute or chronic stenosis of the larynx. *Diagnosis* and *treatment* are those of stenosis from too high tracheotomy or from too prolonged intubation. Immediate tracheotomy is required in the acute stage if there are signs of high obstruction.

## LARYNGEAL STENOSIS

### ACUTE LARYNGEAL STENOSIS

Acute stenosis may result from any of the acute infections, diphtheritic or nondiphtheritic, which are responsible for edema of the subglottic region, from inflammation secondary to the inspiration of a vegetal foreign body such as a peanut, and especially after instrumentation in the removal of such an object, from noninflammatory edema resulting from allergic factors or cardiorenal disease and from a foreign body lodged in the larynx.

**Treatment.** This consists in immediate provision of an airway by intubation or tracheotomy, after which appropriate medical treatment can be instituted.

### CHRONIC LARYNGEAL STENOSIS

Chronic laryngeal stenosis is a frequent sequel of high tracheotomy, i.e., a tracheotomy in which the first tracheal ring or the cricoid cartilage has been damaged. It is a rare complication of tracheotomy when care is taken to keep these two structures intact. The various laryngeal diseases which may be responsible for chronic stenosis include laryngeal diphtheria, acute laryngitis, syphilis, tuberculosis, burns by roentgen rays or radium, and external trauma.

**Pathology.** Scarring and stenosis develop in the subglottic region, and at times there is necrosis of cartilage.

**Clinical Manifestations.** These are generally limited to inability to decannulate the tracheotomized patient or to extubate the intubated patient. When neither intubation nor tracheotomy has been done, there will be dyspnea with audible stridor and indrawing

at the suprasternal notch and at the supraclavicular and intercostal spaces.

**Diagnosis.** Diagnosis is by direct laryngoscopy, supplemented by palpation of the larynx and by roentgenographic examination. The *prognosis* for eventual cure is good, though many patients require treatment for months or years.

**Treatment.** Treatment depends upon the severity of the condition. In the milder cases replacement of the tracheotomic cannula by a smaller one, and occlusion of this tube with a cork (at first a partial occlusion and then a complete one), will re-educate the patient to breathe through the mouth and permit removal of the cannula. If this is not successful, dilatation through a direct laryngoscope may accomplish the desired result. Such dilatation should not be done at too frequent intervals, and each series of dilatations should be followed by a period of rest. When neither of these methods has sufficed to re-establish adequate breathing through the larynx, laryngostomy must be done.

## NEOPLASMS OF THE LARYNX

### BENIGN TUMORS

#### PAPILLOMA

This is the most common benign tumor of the larynx in children. The lesions may grow profusely from any portion of the larynx, though usually from the vocal cords. The tumor rarely, if ever, becomes malignant, and often disappears after puberty. Initially, the only *symptom* is hoarseness; but if the condition is allowed to persist, there is likely to be dyspnea; asphyxia has occurred in unrecognized cases. The *diagnosis* may be made by direct laryngoscopy during the stage of hoarseness, even in an infant. The lesions are pinkish, warty tumors, which scalp off easily when grasped with forceps. The diagnosis should be confirmed by histologic examination.

The best *treatment* is superficial removal of the tumors by forceps through the direct laryngoscope. Care should be taken not to damage normal tissues. Cure will ultimately be obtained, even though at first there is usually rapid recurrence. The disease is self-limited, and eventually the tendency to recurrence will cease. If recurrence is too rapid to be kept under control by this method, and asphyxia threatens, a tracheotomy should be done; the tracheotomic cannula should be left in place while the tendency to recurrence

persists. More extreme therapeutic measures such as radical surgical excision or intensive irradiation are absolutely contraindicated.

#### FIBROLIPOMA

This is a rather rare tumor of the larynx which, though histologically benign, may cause death by asphyxia unless it is removed while still small. In one of the author's patients a large tumor of this kind had so deformed the larynx that chronic stenosis persisted, though the patient's life was saved by tracheotomy. The tumor was extirpated without damage to the larynx.

#### VOCAL NODULES

These are small tumors which occur in children at the junction of the anterior and middle thirds of the vocal cords. They are generally bilateral. They have been called "screamer's nodes" or "singer's nodes." The only *symptom* is slight hoarseness. The nodules may be removed by a small cupped forceps under direct laryngoscopic view.

### OTHER BENIGN NEOPLASMS

During childhood, angiomas and adenomas, as well as various "benign tumors of inflammatory origin" such as hematomas and cysts, may occur in the larynx.

#### MALIGNANT TUMORS

Malignant tumors of the larynx are rare in childhood; epithelioma and sarcoma occasionally occur. *Treatment* is the same as in adults, namely, radical surgical excision or irradiation, the method depending upon the location and extent of the process.

## FOREIGN BODIES IN THE LARYNX, TRACHEA AND BRONCHI

The air passages of children are frequent sites for the lodgment of many kinds of exogenous foreign bodies; the carelessness of adults is the most important contributory factor.

**Pathology.** The changes produced by foreign bodies depend upon their character and upon the degree of obstruction of the air passage. A sharp or irritating object lodged in the larynx will produce severe edema and later suppurative perichondritis. In the bronchus a nonobstructive foreign body may produce little pathologic change, whereas an ob-

structive object will produce atelectasis and later bronchiectasis, pulmonary abscess or empyema. On the other hand, a vegetal object, such as a peanut, may produce immediately a generalized inflammatory condition involving not only the portion of the tracheobronchial tree obstructed, but also the entire respiratory tract. Pneumonia, contrary to popular opinion, does not as a rule occur as the result of lodgment of a foreign body in the air passages.

**Clinical Manifestations.** The initial symptoms of a foreign body in the air passages are choking, gagging, wheezing or cough. After the initial period there is often a symptomless interval which may last for hours, days or weeks. By the time symptoms reappear the initial ones may have been forgotten. The secondary symptoms usually give a clue to whether the foreign body is lodged in the air or food passages, and may indicate the level of lodgment. On occasion, however, dysphagia may occur from the swelling which results from lodgment of a foreign body in the region of the larynx, and foreign bodies in the upper esophagus may cause symptoms referable to the air passages by compression or by the overflow of food or secretions into the larynx. The symptoms localizing a foreign body to the larynx, trachea or bronchi are discussed below.

#### LARYNGEAL FOREIGN BODY

**Clinical Manifestations.** A foreign body in the larynx causes hoarseness, a cough which soon becomes croupy, and aphonia. Hemoptysis, dyspnea with wheezing, and cyanosis may occur. Obstruction resulting from the foreign body or the combination of it and the inflammatory reaction to it may prove fatal if the signs of high respiratory tract obstruction are not promptly recognized and appropriate treatment given.

**Diagnosis.** Roentgenographic and direct laryngoscopic examinations reveal the presence of a foreign body in the larynx. An opaque foreign body in the neck will be clearly demonstrated on a lateral roentgenogram. When it is lodged anteriorly, it is obviously in the larynx; when it is behind the soft tissue shadows of the larynx, it is in the hypopharynx or the cervical esophagus. The plane in which the foreign body lies is another differential point in its localization. If it lies in the sagittal plane, it is in the larynx. If it is in the coronal plane, it is probably in the food passage. Even if the foreign body is nonopaque, indirect evidence of its presence

may be afforded by the roentgenographic examination. Films should always be taken from both the lateral and the anteroposterior projections, although the lateral projection is generally the more useful. In some instances administration of a small amount of opaque material will also be helpful. Direct laryngoscopy will confirm the diagnosis and provide access for instrumental removal of the foreign body. When there is a severe degree of dyspnea, it may be advisable to do a tracheotomy prior to the laryngoscopic examination.

#### TRACHEAL FOREIGN BODY

Though a foreign body in the trachea may be responsible for cough, hoarseness, dyspnea and cyanosis, the characteristic signs are the audible slap, the palpatory thud and the asthmatoïd wheeze. The *diagnosis* of tracheal foreign body may occasionally be made from the symptoms, physical signs and roentgenogram of the chest, but in most instances a definite diagnosis can be made only by bronchoscopy.

#### BRONCHIAL FOREIGN BODY

**Clinical Manifestations.** The initial symptoms are usually similar to those of foreign bodies in the larynx and trachea. Cough, blood-streaked sputum, and metallic taste in the case of metallic foreign bodies, are other symptoms which may be produced by bronchial foreign bodies. The degree of obstruction produced by a bronchial foreign body is a determining factor in the symptomatology as well as in the pathologic changes. A *non-obstructive* foreign body may produce few symptoms even after prolonged sojourn. An *obstructive* foreign body quickly produces symptoms and signs and pathologic changes. When there is only a slight obstruction, a wheeze will be noted. When obstruction is of greater degree, obstructive emphysema or obstructive atelectasis will be produced; if either is allowed to persist, chronic bronchopulmonary disease is liable to be a sequel. When both main bronchi are obstructed, there will be severe dyspnea and even asphyxia. If the foreign body is vegetal, as, for example, a peanut, a severe condition known as *vegetal bronchitis*, or *arachidic bronchitis*, will result. This is characterized by cough, a septic type of fever, and dyspnea. Chronic pulmonary suppuration may be expected when a bronchial foreign body has been present for a long time.

**Diagnosis.** In the diagnosis of a bronchial foreign body the symptoms will depend upon

the stage in which the patient is seen. The possibility of a foreign body as an etiologic factor must be considered in every child with an acute or chronic pulmonary lesion regardless of whether there is a history of a foreign body accident. The physical signs of bronchial obstruction from foreign bodies include limited expansion, decreased vocal fremitus, impaired (atelectasis) or hyperresonant (emphysema) percussion note and diminished breath sounds distal to the foreign body. When there is complete obstruction, with a so-called drowned lung or with atelectasis, there is absence of vocal resonance and vocal fremitus, which may lead to an erroneous diagnosis of empyema. Varying degrees of tympany may be noted over areas of obstructive emphysema, which may persist for a time. Rales are more likely to be on the uninvaded side, but may also be present on the invaded side.

In order to understand the physical signs and the roentgenographic appearance of bronchial obstruction it is necessary to think of the fundamental principles of hydraulics, and to recognize the analogy between the types of valvular obstruction produced by foreign bodies and the different types of valves used in pipes (Fig. 216). What is considered a *first-degree* obstruction may be compared to a bypass valve, which allows passage of air or fluid in both directions, with only slight interference. In such cases a *wheeze* will be produced. In a *second-degree* obstruction there is sufficient interference with the passage of air to permit it to go in one direction only. A "check-valve" action of this sort in the bronchial

tree depends primarily upon the physiologic expansion of the bronchus on inspiration and its contraction on expiration. If the lumen is obstructed by an object which is of just the right size to cause complete obstruction in the expiratory phase, but to allow air to pass in the inspiratory phase, air will enter the distal portion of the lung on inspiration, but little or none will escape during expiration. This type of obstruction produces *obstructive emphysema* (Fig. 217). If blockage of the bronchus is complete, either by complete corking of the bronchus by the object itself or by an obstruction produced by the foreign body in combination with the inflammatory swelling of the bronchial mucosa, a stop-valve obstruction results, and the air in the distal portion of the lung is soon absorbed, leaving an area of *obstructive atelectasis* (Fig. 218). These phenomena are most readily appreciated by observation under the fluoroscopic screen. In a bypass valve obstruction there is little or no roentgenographic evidence produced by a non-opaque foreign body.

When there is a check-valve type of obstruction, the presence of *obstructive emphysema* makes it possible to localize a bronchial foreign body. The obstructed lung will remain expanded during expiration, while the heart and mediastinum will shift to the opposite side as the unobstructed lung empties. The diaphragm is low, flattened and fixed on the obstructed side, while its excursion will be free and even exaggerated on the unobstructed side. The differences between the two lungs are much more evident on expiration than on inspiration. If a permanent record is desired, two films should be taken, one on full inspiration and one at the end of expiration.

When there is complete obstruction of the bronchus, producing *obstructive atelectasis*, the heart and mediastinum are drawn toward the obstructed side and remain there during both phases of respiration.

FIG. 216. Schema showing mechanism of production of obstructive emphysema and obstructive atelectasis by a bronchial foreign body.

FIG. 217. Obstructive emphysema produced by a vegetal foreign body in the right bronchus of a child 15 months of age. Note that the emphysema is best demonstrated by the film taken on expiration.

The diaphragm on the obstructed side remains high, while that on the unobstructed side moves normally. Films taken at the end of inspiration and of expiration will show only the slight difference resulting from the filling and emptying of the unobstructed lung. After the physician has observed these phenomena under the fluoroscope and has come to appreciate the principles of the valvular mechanisms, it is much easier for him to understand the physical signs produced.

Opaque foreign bodies are clearly revealed on the roentgenogram. It is necessary to take films from both the anteroposterior and the lateral positions, with a sufficiently heavy exposure in the anteroposterior view to show a foreign body behind the heart.

**Prognosis.** Foreign bodies in the air passages which are not removed are sooner or later fatal in the majority of instances. Only 2 to 4 per cent of foreign bodies are coughed up spontaneously. About 99 per cent of them can be removed safely by the skilled bronchoscopist, and at least 98 per cent of patients so treated should recover completely when the foreign body is removed.

**Prevention.** Much can be done to avoid foreign body accidents. If small objects are kept out of the reach of children, if children too young to masticate are not given candy containing nuts, and if toys which contain small parts loosely attached are not given to children, many serious cases of foreign body in the air passages will be prevented. Beads, the button box and coins should not be given to children as playthings. Safety pins should not be left near the baby's crib; if they are left within reach, they should always be closed. The closed safety pin is not a dangerous foreign body, but the open one is among

the most dangerous, and the most difficult to remove safely. Adults should not set a bad example by holding pins or other objects in the mouth. The impulse to imitate is strong in a young child; frequently foreign body accidents occur because a baby or young child has imitated an adult by putting foreign objects in his mouth.

**Treatment.** The treatment of foreign body in the air passages consists in removal by direct laryngoscopy or bronchoscopy, with due consideration for the mechanical problem involved in the particular case. In some instances treatment of complicating conditions may be of equal importance. Removal

FIG. 218. Foreign body lodged in left main bronchus, producing atelectasis of entire left lung. Note that the heart is drawn completely into the left chest.

of opaque foreign bodies lodged in the peripheral bronchi should be performed under the biplane fluoroscope. Any secondary infection should be treated with appropriate antimicro-

bial agents as indicated by laboratory sensitivity tests of the pathogenic organism.

CHEVALIER L. JACKSON

## ACUTE INFECTIONS OF THE LARYNX

### GENERAL CONSIDERATIONS

Acute infections of the larynx are of relatively greater importance in infants and small children than in older children. This is true in part because of a somewhat greater incidence in the younger age group, but principally because the younger child has a relatively smaller airway which predisposes to greater respiratory distress.

Acute infections of the larynx are rarely isolated lesions, but are usually associated with some involvement of the adjacent portions of the respiratory tract. However, when there is sufficient involvement of the larynx to produce symptoms, the laryngeal part of the clinical picture is likely to overshadow other manifestations, owing to the severe effects upon vocalization and breathing.

Presumably any of the bacterial and viral pathogens of the respiratory tract can be responsible for laryngeal infection (see Etiologic Considerations of Newly Isolated Viruses, p. 746). None of them, including the diphtheria bacillus, produces a sufficiently characteristic lesion to permit an etiologic deduction from clinical examination alone. The manifestations of hoarseness, aphonia, stridor and inspiratory dyspnea, characterized by suprasternal, substernal, subcostal and intracostal respiratory retractions, are common to infections of whatever etiology. An absolute diagnosis can be established only by laryngoscopic and bacteriologic examinations.

Although an exact classification of acute laryngeal infection is not possible, there are several clinical varieties which, because of etiologic and therapeutic differences, would seem to justify the following classification:

- Acute diphtheritic laryngitis (p. 415)
- Acute spasmodic laryngitis
- Acute nondiphtheritic infections
  - Laryngitis
  - Epiglottitis
  - Laryngotracheobronchitis

### ACUTE SPASMODIC LARYNGITIS

#### (CROUP DIATHESIS)

Acute spasmodic laryngitis, or spasmodic croup, is a self-limited, but usually recurrent,

catarrhal inflammation in which the severity of the laryngeal spasm is out of proportion to that of the infection. The laryngeal involvement comes on suddenly, almost invariably during the night, and is, as a rule, preceded by a mild upper respiratory tract infection. Certain children seem to be especially predisposed to spasmodic laryngitis, and in some instances there is a familial predisposition. The "nervous type" of child is more often affected than is the phlegmatic type. Spasmodic laryngitis is uncommon after five or six years of age and is relatively common only between the ages of two and four years.

**Clinical Manifestations.** Symptoms of the attack may be preceded by moderate coryza and hoarseness for several hours, or the child may have been put to bed apparently entirely well. Less frequently laryngitis, accompanied by fever and a somewhat croupy cough, precedes the spasmodic symptoms. Early in the night, either after gradually increasing dyspnea and some cough or suddenly, the child awakens with a characteristic barking, metallic cough and noisy inspirations. He sits up in bed, struggling for breath, obviously frightened, and often grasps at his throat because of the feeling of oppression and impending suffocation. His face is congested, his expression anxious, his lips and extremities may be cyanotic, and his alae nasi and accessory muscles of respiration move with each stridulous inspiration. The voice is hoarse, the pulse accelerated and the skin moist. There may be little elevation of temperature, usually not over 101° F., but prostration is present. The dyspnea increases with excitement or without discoverable reason. After several hours the severity of the spasm and of the other symptoms diminishes, although more than one attack may occur during the night. By the following morning the evidence of laryngospasm has disappeared, and only slight hoarseness and loose cough remain; the child does not otherwise appear to be seriously ill. Another, but usually less severe, attack may occur upon the next night and occasionally upon the third night unless they are prevented by treatment.

The foregoing description is of severe cases.

In milder ones there may be only a croupy cough and a moderate degree of laryngospasm and dyspnea.

The prognosis is good.

**Diagnosis.** In *diphtheritic laryngitis* the onset is gradual; hoarseness and stenosis become progressively worse; fever and decided depression of strength are more constantly present, and the cough is not so barking. The laryngospasm of *tetany* is usually of momentary duration and may be repeated many times during the day; carpopedal spasm may be associated; and the blood calcium is low. The differentiation from acute laryngitis is described on page 416.

**Prevention.** Prophylactic treatment should be given when a child known to be subject to attacks of croup has hoarseness or a suspicious cough during the daytime. A subvomiting dose of syrup of ipecac (0.5 to 1 cc.) and a sedative dose of phenobarbital (15 to 30 mg., or  $\frac{1}{4}$  to  $\frac{1}{2}$  grain) should be given shortly before bedtime and the sleeping room kept moderately warm (70° F.) and well humidified. Similar treatment may be given for two or three evenings after an attack to prevent subsequent attacks. When there is a chronic infection of the upper respiratory tract, efforts should be made to eradicate it. Cold air should be avoided during respiratory infections; some children subject to croup cannot sleep in cold, well ventilated rooms without having an attack.

**Treatment.** Treatment consists in relief of the spasm with an emetic such as syrup of ipecac, placement of the child in an atmosphere of high humidity, and administration of a sedative after vomiting has been induced. Doses of syrup of ipecac of 2 to 4 cc. for children two to four years of age are usually adequate to induce vomiting, but may be repeated not more than once or twice at intervals of twenty to thirty minutes. After the child has vomited and there is no nausea, phenobarbital may be given if he is kept under close observation for respiratory obstruction. Intubation is rarely, if ever, necessary in spasmodic laryngitis.

## ACUTE NONDIPHTHERITIC INFECTIONS

### ACUTE LARYNGITIS, EPIGLOTTITIS AND LARYNGOTRACHEOBRONCHITIS

Most acute infections of the larynx involve to some degree the adjacent tissues above and below the glottis. In the majority of instances, however, the involvement seems to be prin-

cipally in the larynx with varying degrees of subglottic edema. Less often the involvement is predominantly in the supraglottic area and is termed epiglottitis. At times the inflammation extends into the trachea and bronchi and even into the bronchioles, when the term "laryngotracheobronchitis" is used. The clinical pattern of each of these anatomic lesions is sufficiently characteristic to justify separate designations.

*Acute laryngitis*, which is somewhat more frequent in children than in infants, may be caused by a variety of viral or bacterial agents. The majority of them appear to be viral in origin (See Myxoviruses, p. 747). The most common bacterial pathogen is type b *Hemophilus influenzae*; in some instances other organisms such as the beta hemolytic *Streptococcus*, *Pneumococcus* and *Staphylococcus aureus* may also be causative. Laryngitis may also be a manifestation of scarlet fever, influenza or measles. Noninfectious laryngitis may at times result from excessive crying or shouting or the inhalation of coal gas, dust, and the like.

*Acute epiglottitis* is also most often caused by type b *H. influenzae*. The infection may occur at any age, but most often in young children.

*Acute laryngotracheobronchitis* is a term that was reserved in the past for a characteristic syndrome involving the laryngeal and tracheobronchial passages in which there is a definite exudative reaction. In some instances the tracheobronchial tree is practically filled with a purulent exudate; in others the secretions dry rapidly, become extremely viscid and obstruct the air passages. This type of involvement has become much less common in recent years. By contrast, infections of the laryngotracheobronchial area with little or no exudative reaction are relatively frequent. For this reason it seems preferable to use the anatomic designation for all infections involving these portions of the respiratory tract, irrespective of the exudative response. These infections occur principally in the first three to four years of life. A number of viral and bacterial agents may be causative; the bacterial ones include *H. influenzae*, hemolytic streptococci, staphylococci and pneumococci.

**Clinical Manifestations.** *Acute laryngitis*. Evidence of laryngeal inflammation usually follows that of an upper respiratory tract infection by one or more days. The progression and the severity of the laryngeal symptoms vary considerably. In mild cases there are

hoarseness, a low grade fever and only mild constitutional symptoms. There is no dyspnea. In the more severe cases there is progression of the disease during the first two or three days. The patient becomes increasingly hoarse, and there may be aphonia. At this stage, dyspnea is usually present, and characteristically there are suprasternal and infrasternal retractions and stridor. The intake of air is decreased, owing to the relatively greater obstruction during the inspiratory phase of respiration. The temperature is usually elevated, often being as high as 103° to 105° F. The child may be prostrated in extreme cases. There are varying degrees of pharyngeal inflammation. Direct laryngoscopy reveals redness and swelling of the vocal cords and adjacent tissues and especially of the subglottic area.

**Acute epiglottitis.** The onset is sudden with sore throat, high fever, prostration and severe inspiratory type of dyspnea. The rapidity of the onset and of the course is characteristic and emphasizes the necessity for early recognition and, in most instances, tracheotomy. In small children who cannot complain of the soreness of the throat the only manifestations may be the extreme restlessness of air hunger, prostration and fever. The redness and swelling of the epiglottis and the immediately adjacent areas can often be seen by the usual pharyngeal examination. The aryepiglottic folds and arytenoids are usually involved, and for this reason some clinicians prefer to use the term "supraglottic laryngitis." There is usually little or no involvement of the vocal cords. The pulmonary findings are those of high (inspiratory) obstruction with suprasternal and infrasternal retractions and diminution in the intake of air.

**Acute laryngotracheobronchitis.** In most instances there is a preceding history of an acute upper respiratory tract infection for a day or more. In the more fulminating infections, most of which appear to be caused by type b *H. influenzae*, the onset may be abrupt, with high fever, prostration and extreme dyspnea. As noted earlier, there is a variety of clinical patterns. The initial respiratory difficulty is usually inspiratory, owing to the laryngeal involvement, but subsequently there is expiratory embarrassment as the inflammation extends downward into the bronchi and even into the bronchioles. Thus the clinical pattern includes features characteristic of both laryngeal (inspiratory) and bronchiolitic

(expiratory) obstructions. There are hoarseness or aphonia and infrasternal and suprasternal retractions, but when there is generalized obstructive emphysema secondary to bronchitic and bronchiolitic involvement, the retractions are not deep. The breath sounds vary considerably and often are prolonged and harsh in both phases. When the obstruction is practically complete, they may be so diminished in volume as to be barely audible. Similarly there are great variations in the adventitious sounds. Most often there are rhonchi and large rales, but there may be medium and even fine rales. If the infant or child is able to sit, he prefers this position. There is usually a persistent cough, which in the more exudative lesions is loose, rattling and croupy. The temperature is usually high, levels of 104° to 105° F. being common.

**Differential Diagnosis.** Diphtheria must be considered in the differential diagnosis of all acute laryngeal infections, and material secured for direct smear and for culture. Furthermore, though many laryngeal infections are viral in origin, bacterial culture and determination of the sensitivities of any isolated organism to various antibiotic agents are desirable; blood cultures should also be obtained.

**Retropharyngeal abscess** may cause stridor, but there is no hoarseness, and the abscess can usually be recognized by palpation of the throat or by laryngoscopic examination. A *foreign body* lodged in the laryngeal area may simulate laryngitis, and the reaction to a vegetal foreign body, such as a peanut, may simulate laryngotracheobronchitis. In such instances fluoroscopic and bronchoscopic studies are necessary.

**Prognosis.** The outcome in all three conditions depends on the severity of the infection, the age of the patient, the duration of symptoms before treatment is instituted, and the adequacy of treatment. The death rate has been high, especially in *H. influenzae* epiglottitis and exudative laryngotracheobronchitis. In cases treated early a favorable outcome can be expected.

Death occurs from respiratory obstruction and from the infection itself. An airway, when needed, can be provided by tracheotomy, and the infection can usually be controlled by appropriate antibiotic therapy.

Chronic bronchitis, bronchiectasis and pulmonary abscesses are occasional residuals of the infection. Chronic laryngeal stenosis and perichondritis are not common except as the result of improperly performed tracheotomies.

**Treatment.** In all three conditions the principles of treatment are identical, and consist in provision of sufficient air (oxygen) and control of the infection.

Humidification of the inspired air is beneficial in all laryngeal infections, irrespective of their severity, to lessen the irritation and drying of the secretions. Cold humidification is preferable to steam and is best provided in a tent or specially designed room. In the home a "croup tent" can be improvised by using a steam humidifier.

Oxygen therapy should be provided whenever the accessory muscles of respiration are used for breathing; one should not wait for the development of cyanosis.

Antibacterial therapy is indicated in all infections of moderate or marked severity. It is true that many of the infections are viral in origin, and hence will not respond to the therapy, but this cannot be predicted, and the severity of the infection justifies the therapeutic trial. Initially, material should be obtained for culture, preferably through a laryngoscope; otherwise both nasopharyngeal and pharyngeal cultures should be secured, the latter while the patient is coughing. Therapy should not be delayed, however, until the results of the culture are available. The initial therapy should be effective against the various possible bacterial pathogens (broad-spectrum). Subsequently when the report of the bacterial culture is available, any indicated changes in the prescription may be made. Inclusion of chloramphenicol in the initial therapy would seem justified in view of the frequency with which these lesions and especially epiglottitis and laryngotracheobronchitis are caused by *H. influenzae*.

Tracheotomy can be a lifesaving measure when the obstruction of the airway is severe. The determination of the need for tracheotomy and the timing of it require experience. When it is clear that the patient has an insufficient airway and that the foregoing measures would not be effective quickly enough, a tracheotomy should be performed immediately. In general, the indications for tracheotomy are the entrance of only minimal amounts of air into the lungs in spite of breathing activity, prostration with extreme pallor and/or cyanosis, and cardiac failure. However, the experienced clinician appreciates that a child can be in considerable respiratory distress and still respond adequately to oxygen, humidification and antibacterial therapy. In acute severe epiglottitis,

tracheotomy is required in 50 per cent or more of cases and should not be delayed when the indications are clear. In laryngotracheobronchitis, tracheotomy may be necessary to provide not only an airway, but also a means for aspiration of the trachea.

One of the commonest errors in the technique of tracheotomy is making the tracheal incision too high or even cutting the cricoid cartilage. This is perhaps the commonest cause of difficult decannulation and chronic stenosis. On the other hand, the tracheotomy incision can be made too low; it is sufficiently low if it is located just below the first tracheal ring. A tracheotomy can be more safely and satisfactorily performed if an intubation tube, a Mosher "life saver" or a small bronchoscope is inserted into the larynx for maintenance of quiet breathing while the operation is being performed.

For the after-care of tracheotomy a nurse, properly instructed and preferably experienced in the care of such patients, must be constantly in attendance. Not only must the inner cannula be removed and cleaned frequently, but also a small catheter should be used to aspirate the outer cannula and the tracheobronchial tree as often as necessary to keep the airway open. If dyspnea or restlessness persists after tracheotomy, the lower airway must be investigated with a small bronchoscope, which may be introduced through the tracheal fistula. In many cases the obstruction can be removed if a few drops of saline solution are dropped into the tracheal cannula with a medicine dropper before aspiration.

The child requires complete rest and must not be disturbed by unnecessary examinations or unnecessary uncomfortable therapeutic measures. Dehydration should be combated by administration of liberal quantities of fluid, preferably by mouth. Opiates and atropine should not be used, owing to their tendency to dull the protective cough reflexes and to dry secretions. If signs of cardiac failure appear, digitalization is indicated.

For neoplasms of the lung, see page 1350.

### MALFORMATIONS OF THE TRACHEA, BRONCHI AND LUNGS

*Tracheo-esophageal fistula* is the most important congenital anomaly of the trachea (p. 640). Rarely the trachea may be absent, or there may be tracheal stenosis of varying degrees. *Tracheal compression* may be produced by an anomalous aortic arch or other large vessel (p. 877). *Tracheal diverticula* are blindly ending bronchus-like projections arising from the trachea. In rare instances they may terminate in normal-appearing lung tissue (tracheal lobe). Other tracheal abnormalities are mentioned on pages 771 and 1237.

*Bronchial cysts* are usually located in the region of the bifurcation of the trachea.

*Anomalous fissures and lobes of the lungs* are frequently observed roentgenographically and at autopsy, but are usually of no clinical significance. The so-called azygos lobe is actually a part of the right upper lobe. During fetal development the azygos vein normally shifts medially into the mediastinum and onto the vertebral column. If such a migration fails to occur, the vein cuts into the growing right upper lobe, leaving a deep azygos fissure, which separates the more medially placed azygos lobe from the remainder of the right upper lobe; there is no abnormality of the bronchial tree.

*Congenital absence of both lungs* is extremely rare. Bilateral hypoplasia of the lungs may occur in anencephalic monsters or may be associated with congenital diaphragmatic hernia; in the latter instance the lung on the side of the defect in the diaphragm shows the greatest reduction in size.

*Unilateral pulmonary agenesis or hypoplasia* is compatible with life. The heart and other mediastinal structures are shifted to the affected side, and the contralateral lung is hyperexpanded and partially fills the thoracic cavity on the involved side. The stem bronchus on the affected side may be absent, rudimentary or of normal length and covered by a small rudimentary lung. Other associated extrapulmonary anomalies, especially hemivertebrae, may be present.

*A lower accessory lung* is a rare congenital

anomaly. The accessory lung does not communicate with the tracheobronchial tree, and its blood supply is usually systemic rather than pulmonary in origin. It is almost always situated at the base of the left lung, rarely below the left diaphragm. Its structure varies from normal-appearing lung to that of a cystic space containing bronchial elements, but few or no alveoli.

Instances of *anomalous (nonpulmonary) circulation* in portions of one or the other of the two lower lobes have also been observed; in these cases there is a bronchial communication, but some maldevelopment of it. The blood supply is from the systemic circulation by way of an anomalous artery from the aorta. The lung tissue is usually replaced by multiple bronchial cysts or bronchiectatic cavities. Surgical removal of the involved lung is indicated.

*Cysts of the lungs* are occasionally present in infants early in the newborn period and may be single or multiple, restricted to one lobe or distributed in two or more lobes. There is lack of agreement concerning the origin of many of them. It has been considered that those with an epithelial lining were congenital anomalies and that those without such a lining were the result of post-natal destructive processes. There is doubt whether this distinction is valid or whether the presence of cartilage in the wall of a cyst is in itself evidence of a congenital origin.

Cysts of congenital origin have been described in association with adenomatoid malformations of the lungs (Fig. 221). The lesion, which apparently is most often limited to one lobe, may initially appear on the roentgenogram as a solid structure. The bronchi are malformed. As the lobe is irregularly aerated during the first few days of life, air accumulates in the potential cystic structures. These progressively enlarge and may cause severe respiratory distress.

Most cystic structures in the newborn period or later are acquired and result from destruction of the pulmonary architecture. This may occur during artificial respiration (see Pneumomediastinum, p. 328) and perhaps on occasion might be responsible for an accumulation of air (cyst) within one or more lobes (see Bullous Emphysema, p. 807). Partial blockage of a bronchus with creation of a ball-valve type of mechanism will permit

FIG. 219. The lobar and segmental bronchi and the subdivision of the lungs on the basis of bronchial distribution.

It has become significant to subdivide the lungs into parts smaller than the lobes for the sake of more accurate localization of pathologic lesions and of more economical resections in such diseases as bronchiectasis and tuberculosis. Although the lobes are classically identified by the interlobar fissures, it is obvious that a lobe is the complete branching of the bronchus which enters it. The real basis of the division of the

FIG. 220. Ventral and right lateral projections of the thorax in a child 20 months of age, showing normal roentgenographic appearance. The diagrams identify landmarks and indicate the correspondence between various parts of lung fields and the respective lung lobes. In lateral projections, lesions are readily localized to particular lung lobe or lobes. In ventral and dorsal projections there are large areas of the lung fields in which observed lesions might be in either of 2 lung lobes. In lateral projections, relationships to the heart shadow serve to distinguish between right and left leaves of the diaphragm. (Courtesy of Dr. W. Edward Chamberlain, Professor Emeritus of Radiology, Temple University School of Medicine.)

lungs into lobes is bronchial distribution. In a similar way, each lobe is subdivided by the branches coming from the lobar bronchus. For example, there are usually 3 branches of the right upper lobe bronchus, each of which supplies or branches out to form a definitive part of the lobe. The term "bronchopulmonary segment" is applied to that portion of a lobe supplied by a branch of the lobar bronchus. Smaller subdivisions can be made on the basis of the distribution of the branches of the segmental bronchus. These smaller subdivisions are referred to as "subsegments." Each segment is named according to its position in the lobe of which it is a portion. For example, the 3 segments of the right upper lobe are anterior, apical and posterior segments of the right upper lobe. The bronchi are correspondingly named anterior, apical and posterior segmental branches of the right upper lobe bronchus.

At an intersegmental plane the alveoli at the periphery of one segment are separated from the alveoli of the adjacent segment by a small amount of fibrous connective tissue. It is of interest to note that the tributaries of the pulmonary veins are located in the intersegmental planes and that the branches of the pulmonary arteries follow along the bronchial branchings. (Prepared by Dr. John Franklin Huber, Professor of Anatomy, Temple University School of Medicine.)

FIG. 221. Cysts of the lung. Congenital adenomatoid malformation in an infant 6 months of age. Respiratory distress was evident shortly after birth and became progressively more severe. Multiple cysts of varying sizes are demonstrated in both lung fields. At this time several sequential films indicated increasing size of several of the cysts, and the larger ones on the left side were removed surgically. There was temporary benefit. Subsequently additional cysts were removed, again with temporary relief of the dyspnea. The infant died at 12 months of age. Autopsy revealed multiple polyps in the small intestine and cysts in both kidneys in addition to the pulmonary malformations.

retention of an increasing amount of air. Under such circumstances, whether the obstruction is inflammatory or purely mechanical and whether it is intrabronchial or extra-bronchial, a so-called tension cyst is created. In other circumstances connection with the tracheobronchial tree is broken, and the accumulation of air (bullous emphysema) remains for long periods of time before it is finally absorbed and the architecture of the lungs is realigned. A wide variety of factors can be responsible for such obstructions of the bronchi, some of which may be congenital in origin, but the majority of them are probably the result of postnatal disturbances, usually inflammatory. An unusual association with cytomegalic inclusion disease has been recorded. The cysts may be filled entirely with air or fluid or with a combination of them.

Most cysts eventually disappear without interference, but when a tension cyst continues to expand and compress the other lobes, it is usually necessary to remove the lobe containing it. However, even such cysts may establish an equilibrium with the un-

involved portions of the lung, become closed and eventually disappear. For this reason decision for surgical removal must be based on the degree of respiratory embarrassment and whether it is progressive.

## BRONCHITIS

### ACUTE BRONCHITIS

Acute infection of the bronchial tree seldom if ever occurs as a primary infection or as one limited to this portion of the respiratory tract. Since the trachea is nearly always involved, it would be more exact to speak of acute tracheobronchitis. The term "capillary bronchitis" (bronchiolitis) has been used to describe an acute and serious infection which is less common in children than in infants, and in which the principal manifestations are located in the bronchioles. Though a number of pathogenic agents may be responsible for this type of infection, it appears that most of them are viruses.

Acute tracheobronchitis, or acute bronchitis, as it will be termed here, is usually secondary to an acute nasopharyngitis or to such specific infections as measles, pertussis, typhoid fever, influenza, scarlet fever and diphtheria. A variety of organisms have been isolated from acute infections of the bronchi, the more common ones being the pneumococci, hemolytic streptococci, staphylococci and *H. influenzae* bacilli. However, their presence does not, in itself, indicate that they are acting as pathogenic agents.

There are a number of predisposing causes, such as undernutrition, chronic infection of the upper respiratory tract, allergy and rickets. Age is an important factor, bronchitic infections being more frequent in the first three or four years of life than later. A high incidence within family groups is frequently noted. Certain children seem to be especially predisposed to bronchial infections.

**Clinical Manifestations.** The manifestations of bronchitis are usually preceded by an upper respiratory tract infection. The severity of the onset varies considerably. There is usually some fever, but the temperature is rarely over 102° F. Cough is the most constant symptom. Initially it is dry, at times paroxysmal, and it may be harsh and brassy. Older children may complain of a sense of dryness in the throat and of soreness and discomfort in the chest. In one or two days, when bronchial secretions become established, the cough becomes looser, and, in children

old enough to expectorate, there is sputum which rapidly becomes purulent. In infants and young children the secretions are swallowed or are aspirated into the trachea and bronchi. Vomiting is at times induced by the violence of the cough or by the gagging reflex excited by the large amounts of secretion in the throat. Constitutional symptoms are as a rule not marked.

The physical signs vary with the stage of the disease. Initially there may be none. Later, rhonchi and coarse, moist rales can be heard over the entire chest, the rales being especially prominent over the lower posterior portions. The fremitus produced by the secretions in the larger bronchi can often be felt on palpation and at times may be heard even at a distance from the chest. The percussion note is not affected. There is no relation between the extent of the rales and severity of the disease except when there are medium or fine rales as evidence of bronchiolar involvement.

The acute symptoms are usually limited to five or six days, but cough and expectoration tend to persist for another week or two. The course may be more prolonged in infants, especially in debilitated ones. Bronchitis, per se, is rarely fatal, and serious complications from it are not common. Diffuse pneumonitis is more likely to occur in infants, but is much less frequent since the availability of specific antibacterial agents. Other complications of respiratory infections, such as otitis media and laryngitis, occasionally occur. Pulmonary abscess is an infrequent complication, and chronic bronchitis is rarely a residual.

**Treatment.** The child should be confined to bed as long as there is fever. Infants should be picked up and held frequently or should have their position changed from time to time to facilitate drainage and thus lessen the danger of pneumonia. The room should be adequately ventilated, but cold air is distinctly irritating to the respiratory mucosa during these infections. The humidity of the room should be maintained at 50 per cent or higher; for this purpose cold humidification is preferable to steam. Inhalations of carbon dioxide and oxygen for five to ten minutes every half-hour or hour may be especially effective in loosening thick and viscid secretions. Other expectorants are less efficient and are of little value, especially during the acute stage. Ammonium chloride may be prescribed for older children; in the subacute phase, syrup of hydriodic acid may be given in doses of 2 cc. to infants and of 4 cc. to older chil-

dren. It is especially well taken when combined with half or equal quantities of syrup of cherry. Acetylsalicylic acid, 60 mg. (1 grain) per year of age, is useful in allaying the discomfort and quieting the child. Atropine or belladonna is contraindicated because of its effect in drying the pulmonary secretions and thus making them more tenacious and difficult to expel. Morphine and other opium derivatives should be avoided when there is extensive secretion because of suppression of the cough reflex, which is an important factor in expelling the secretions. When the infant or child is extremely restless and is not quieted by measures designed to clear the respiratory tract of secretions or by administration of acetylsalicylic acid, phenobarbital may be given. However, when there are excessive secretions, this should be avoided until the airways have been cleared. If the nose is congested, ephedrine or one of the other shrinking solutions may be used. When there is excessive bronchial secretion which cannot be adequately expelled, bronchoscopic aspiration may be helpful.

Children who have repeated attacks of bronchitis should be thoroughly studied to determine the underlying cause. Such possibilities as chronic sinusitis, infected tonsils and adenoids, bronchiectasis, tuberculosis, allergy and hypogammaglobulinemia should be carefully considered.

### CHRONIC BRONCHITIS

Chronic bronchitis is infrequent among children, and particularly so as an isolated disturbance. Perhaps it occurs most often in association with chronic infection of the nasal accessory sinuses, so-called sinobronchitis. Chronic bronchitis may also be associated with allergic conditions of the respiratory tract, especially when there is hypersensitivity to bacteria. Infrequently certain fungi may be responsible for chronic bronchitis. It may also be associated with chronic cardiac conditions when there is some degree of myocardial failure. Irritation of the bronchi from aspiration of dust, lint or gaseous fumes may be a contributing factor.

**Clinical Manifestations.** The chief symptom is cough. It is likely to be more troublesome shortly after the child has gone to bed and may be of such severity that it disturbs sleep; it is also frequently marked in the morning. During periods of exacerbation the cough tends to be loose, and there is apt to be considerable expectoration. The constitutional symptoms vary considerably; there may

be malaise and apathy. Except during acute exacerbations there is usually no fever. The physical findings are not constant. At times there are none, and at other times medium and coarse rales and rhonchi are present, and there may be fremitus on palpation. These signs often disappear after coughing and expectoration.

**Differential Diagnosis.** Roentgenograms of the sinuses and chest are essential, tuberculin and fungus skin tests should be performed, and cultures of the sputum or of bronchial aspirations for bacteria and fungi should be obtained. Bronchiectasis can be eliminated with certainty only by complete visualization of the bronchial tree by bronchography. The possibility of myocardial involvement requires consideration. The majority of cases, however, will be found to be related to infections of the sinuses, with allergy perhaps the next most common cause.

**Complications.** The principal complication is bronchiectasis. Other complications are atelectasis, emphysema, and infection of the tracheobronchial lymph nodes.

**Course and Prognosis.** The course is somewhat characteristic in that the manifestations are exaggerated during the winter and spring months, with considerable improvement during warm weather. There are frequent acute exacerbations, the clinical manifestations being those of acute bronchitis. The prognosis is dependent principally upon the cause and upon the possibility of its eradication.

**Treatment.** Treatment depends upon the cause. When there is no response to therapy, a change to a dry, warm climate may be beneficial. Expectorants, except perhaps carbon dioxide and oxygen inhalations as described under Acute Bronchitis, are of little benefit. Vaccine therapy has been disappointing, although a few patients seem to benefit by desensitization with autogenous vaccines. Antibiotic aerosol therapy has limited usefulness in conjunction with a proteolytic enzyme. Good pediatric care, physical and emotional, is essential.

### PNEUMONIA

No clinical classification of pneumonia is entirely satisfactory. It has been common practice to separate the various clinical forms of pneumonia on the basis of their anatomic distribution, the principal designations being lobar pneumonia, lobular pneumonia or bronchopneumonia, and interstitial pneumonia or bronchiolitis. If separate categories are pro-

vided for the various aspiration pneumonias and for hypostatic pneumonia, most pneumonic infections can be grouped under these anatomic headings.

More or less characteristic lesions are produced by certain etiologic agents. For example, the *Pneumococcus* produces an inflammatory lesion of the mucosa and a marked alveolar exudate, usually without destruction of the mucosal cells or extensive involvement of the interstitial tissues. The gross lesion is a consolidation of all or part of a lobe in the lobar variety, or of scattered lobules in the bronchopneumonic variety. In contrast, viral agents, *Hemophilus influenzae* and certain strains of the viridans group of streptococci invade or destroy the mucous membrane and produce principally bronchiolitis, peribronchiolitis and interstitial lesions. Secondary infections, especially in association with the primary viral infections, are often responsible for suppurative bronchiolitic, alveolar and interstitial lesions. Both the *Staphylococcus* and Friedländer's bacillus tend to destroy tissue and to produce multiple small abscesses.

Most bacteriologic infections can now be identified not only as to the causative agent, but also as to the specific type or strain of a given species. Since such identification or the failure of it has both therapeutic and prognostic significance, there are strong arguments for an etiologic classification. Since, however, it is not possible to identify the etiologic agent in all instances, it is necessary to include a grouping on a pathologic basis. Most of this latter group occur in the period of infancy, and practically all of them fall into the category of acute bronchiolitis or acute or chronic interstitial pneumonitis, and most of them probably are viral in origin.

Within limits a clinical distinction can also be made on the basis of response to antimicrobial therapy. Most of the bacterial infections are susceptible to one of these agents, whereas the viral infections usually are not. The limitations of a distinction on the basis of a therapeutic trial, however, are obvious. Some of the larger viral agents, which may cause pneumonitis, appear to be affected to some extent by the sulfonamides and the so-called broad-spectrum antibiotics. Of equal importance is the variation of antibiotic susceptibility among the different pathogenic bacteria which infect the lungs and even among the strains of a given species, viz., the *Staphylococcus aureus*.

The following classification is presented as a working basis:

#### *Bacterial Infections*

*Pneumococcus*  
*Streptococcus*  
*Staphylococcus*  
*H. influenzae*  
Friedländer's bacillus  
Tubercle bacillus  
*Treponema pallidum*

#### *Viral or Probable Viral Infections*

Bronchiolitis and interstitial pneumonitis  
Primary atypical pneumonia, etiology unknown  
Giant cell pneumonia  
Plasma cell pneumonia  
Influenza  
Q Fever

#### *Mycotic Infections*

Coccidioidomycosis  
Histoplasmosis  
Blastomycosis  
Cryptococcosis  
Mucormycosis  
Nocardiosis  
Sporotrichosis  
Thrush

#### *Aspiration of*

Amniotic contents (fetal anoxia)  
Food  
Foreign bodies  
Zinc stearate  
Dust  
Kerosene  
Lipoid substances

#### *Löffler's Syndrome*

#### *Hypostatic Pneumonia*

### BACTERIAL PNEUMONIA

#### PNEUMOCOCCAL PNEUMONIA

The *Pneumococcus* has been perhaps the principal cause of pneumonia in infants and children. In recent years, however, there has been a sharp decrease in the incidence of pneumococcal pneumonia. The rapid clinical response of most pneumococcal infections to sulfonamide or antibiotic medication and the common practice of administering these therapeutic agents to patients early in the course of an infection apparently prevent many pneumonic infections and mask the diagnosis in other instances.

The lobar type of involvement which is characteristic of pneumococcal pneumonia in adults is the usual response in children beyond the age of infancy. The lobular or disseminated type is relatively more frequent in the first year of life than it is thereafter.

**Etiology.** Some seventy-five types of pneumococci have been identified; type-specific serums have been made for thirty-two of the

first thirty-four types (except XXVI and XXX). In contrast to the frequency with which the lower types of pneumococci are isolated from adults with pneumococcal infections, the majority of those isolated from infants and young children belong in the higher numbered types (Cooper, IV to XXXIII). In patients of all ages the most frequent types in the order of their relative frequency are I, III, VIII, VII, IV, V, XIV, II, VI, XIX. In infants, however, type XIV occurs most frequently. Other common types found in the younger age group are types V, I and XIX.

**Predisposing Factors.** Though pneumococcal pneumonia is often considered a primary infection, mere contact with a case of pneumonia or even the presence of pneumococci in the nose and throat is not sufficient for the production of pneumonia. Factors which temporarily lower *resistance* to infection may make it possible for the pneumococci to get a foothold in pulmonary tissue. Age is a significant factor, the incidence rising sharply after the first month or so of life with a peak during the second year of life and declining rapidly thereafter.

**Epidemiology.** The incidence of pneumonia is at its peak during the late winter and early spring months. Though epidemics have been reported, they have been principally in institutions or military camps. Among the general population in the temperate zones, pneumonia exists as an endemic rather than an epidemic infection. The family is an important epidemiologic unit, although multiple cases of pneumonia infrequently occur in the family. Some or all of the members of the family of a patient with pneumonia usually harbor the homologous type of organism. Some of them will have no obvious infection and apparently serve only as carriers. However, infections of the upper respiratory tract due to the *Pneumococcus* are common in family contacts, and other pneumococcal infections such as otitis media, meningitis and arthritis occur less frequently. It is of interest that the patient convalescing from pneumonia soon loses his virulent strain of pneumococci, whereas members of the family who have not had pneumonia may continue to be carriers for weeks or months.

The blood of most persons contains antibodies against many types of pneumococci. Pneumococcal antibodies in the blood of newborn infants tend to parallel those in the blood of the mother. This pneumococcidal property is apparently lost by the first month of life. Pneumococcal antibodies are found

again in successively higher titers after the first year of life.

**Pathogenesis.** Pneumococci apparently gain entrance to the lungs by way of the respiratory passages and not through the blood stream. They reach the alveoli, where they incite an inflammatory response, characterized in its early stages by an outpouring of edematous fluid in which are numerous pneumococci. This fluid, laden with pneumococci, flows through the openings in the alveolar walls (pores of Kohn), through alveolar ducts and bronchioles into other lobules, and thus rapidly spreads to involve the entire lobe.

**Pathology.** The first stage, that of *engorgement*, usually lasts only a few hours. The lung is heavy, congested, dark bluish-red, but not solidified. Microscopically, the interalveolar capillaries are greatly distended, and the alveoli are filled with a serous exudate containing large numbers of pneumococci and a few red blood cells and neutrophils. In the second stage, or stage of *red hepatization*, the involved lobe is solid and airless. The red color is due principally to engorgement of the capillaries and partly to alveolar hemorrhage. The alveoli contain fibrin, neutrophils, serum, red blood cells and pneumococci. This stage passes rapidly into that of *gray hepatization*. The pleural surface is dull and lusterless, owing to the presence of a film of fibrin. Histologically, the alveoli are filled with fibrin and neutrophils; the interalveolar capillaries are no longer engorged, but are now barely visible. This stage is much more prolonged than the preceding ones, and passes into the final stage of *resolution*. The exudate now softens, and creamy pus can be expressed from the cut surface. Increasing numbers of macrophages appear in the alveolar spaces, the neutrophils undergo necrosis and fatty degeneration, and the fibrin threads are digested and disappear. The clinical crisis cannot be correlated with the stage of resolution; resolution and re-expansion in the untreated case require an additional one to three weeks after the crisis.

Pathologically, bronchopneumonia differs from lobar pneumonia principally in the patchy irregular distribution of the former.

**Clinical Manifestations.** The clinical pattern in children is more variable than in adults. Cases with an abrupt onset and sustained fever, which terminate by crisis after five to nine days, do occur at all ages, but are seen more consistently in older children than in infants and more often when the pneumonic distribution is lobar rather

than bronchial. In general, the onset of the pneumonia itself is abrupt, but is often preceded for several days by symptoms of an upper respiratory tract infection. Symptoms referable to the gastrointestinal tract and to the nervous system are more commonly observed in children than in adults. Vomiting is common in both types of pneumonia; diarrhea and convulsions are more often associated with bronchopneumonia in infants, and meningismus with the lobar variety in older children. Prostration is generally greater in the bronchopneumonic variety and the temperature more remittent in type. There are many variations, however, in the clinical patterns of both forms, and they are frequently indistinguishable on the basis of their clinical course.

Both the onset and course have been materially altered by sulfonamide and/or antibacterial therapy. When such therapy has been administered in the prodromal phase of the upper respiratory tract infection, the typical pattern may be altered or the pulmonary infection may be completely averted. When adequate therapy is instituted within the first two or three days of the pneumonia, the typical clinical manifestations are usually abolished within twenty-four hours.

**Onset.** Prodromal symptoms other than those of an upper respiratory tract infection are usually absent. The chill which is characteristic of the onset in older children and adults is frequently replaced by a convulsion in infants. Fever and respiratory distress usually appear abruptly.

**Fever.** The elevation of temperature is rapid, reaching 103° to 104° F. within a few hours. In older children with the lobar variety the daily fluctuations may not be more than a degree or so, whereas in infants, especially when they have a bronchopneumonia, the daily fluctuations are likely to be somewhat greater. The course of the untreated illness in older children is usually terminated by an abrupt drop in temperature, the so-called crisis, but usually without associated symptoms of collapse. The drop in temperature is frequently by lysis in the untreated disseminated variety.

**Respirations and pulse.** Respiratory rates of 30 to 50 per minute are common in older children, and of 40 to 80 in infants. The respiratory excursion is characteristically shallow in order to lessen pleural pain. In severe cases the accessory muscles of respiration may be brought into use with the result that there is some indrawing of the intercostal spaces.

Movement of the alae nasi is one of the more constant symptoms. An expiratory grunt is more common in older children than in infants.

The pulse rate is increased, but not to the same extent as that of the respiratory rate; instead of the characteristic ratio of 1:4, ratios of 1:2 or 1:3 may be observed. A pulse rate of 140 to 180 per minute is not infrequent in infants, but in itself is not an unfavorable sign if the tension remains good. A weak, rapid pulse and a slow pulse are both grave prognostic signs.

**Cough and expectoration.** Cough is generally present. In the early stage it is usually dry and tends to accentuate the pleuritic pain. In the stage of resolution the cough may become looser and productive, but the characteristic rusty sputum is not often seen in children.

**Pain.** Thoracic pain due to pleural involvement is often present, being accentuated by coughing and respiratory movements. Its frequency in infants is difficult to evaluate, but it is generally assumed that there is less pain in the disseminated form than in the lobar variety. The older child often lies on the affected side to lessen the pain. Not uncommonly the pain is referred to the abdomen and, when there is involvement of the right leaf of the diaphragm, may be referred to the right lower quadrant, simulating that of acute appendicitis.

**Gastrointestinal symptoms.** Vomiting at the onset is a common symptom, but is seldom continued after the first day unless feeding is forced. Initially there may also be a loose stool or two, but persistence of diarrhea is uncommon. The appetite is greatly diminished, although thirst may obscure this fact in infants, since they may continue to take the usual amount of milk.

**Nervous symptoms.** Convulsions are relatively common at the onset in infants, and headache is common in older children. Delirium may occur, especially in association with extremely high fever.

Meningismus is a comparatively common manifestation, especially in the lobar type. Though nuchal rigidity is usually the only manifestation, there may be positive Kernig and Brudzinski signs and even opisthotonos. In such instances the possibility of a coexisting meningitis can be eliminated only by examination of the cerebrospinal fluid.

**Examination of the Chest.** In the very early stage it is often difficult to make the diagnosis of pneumonia by examination of

the chest, but its presence may be suspected by the appearance of the child. Rapid, shallow respirations with associated movements of the alae nasi and sudden onset of high fever are strongly suggestive of a pneumonic infection.

The physical findings of the *bronchopneumonic* variety depend upon the number and extent of the pneumonic areas. When there are only a few small isolated areas, they may not be detected. In the early stage there may be fine or medium-sized rales over the involved areas for a short time, but these are usually missed. When the pneumonic areas become consolidated, there are likely to be neither percussion nor auscultatory changes because of the small areas involved. During the stage of resolution rales may again be present over the involved areas. Pneumonic areas which involve several contiguous lobules are usually detectable by physical examination, the sequence and nature of the physical signs being similar to those of lobar pneumonia.

In the *lobar* variety the pulmonary findings are characteristic after the first day or two of the disease. Before this time the pneumonic area may be missed on physical examination, and the disease may be suspected only from the appearance of the child, or the pneumonic lesion may be suspected on physical examination, but incorrectly localized. Initially there is little or no impairment to percussion over the pneumonic lobe, but there usually is suppression of breath sounds. The apparent exaggeration of the breath sounds in the corresponding lobe of the opposite side is often misinterpreted as tubular breathing and is assumed to be a physical sign of pneumonia. As the stage of congestion proceeds, fine rales are heard over the pneumonic area, but they are present for only a short time and disappear as soon as consolidation has occurred. At this time, usually by the second or third day, there is definite dullness to percussion, and the breath sounds are tubular in quality. The decreased excursion of the chest can be detected by observation and palpation. Pleurisy is practically always present, but a friction rub is not a common finding. At the beginning of resolution rales can again be heard for a day or two, and the signs of consolidation disappear within several days.

Consolidation can usually be demonstrated on the roentgenogram before it is detectable by physical examination. In an occasional case of bronchopneumonia individual lesions are

so small that they may be missed even on roentgenographic examination.

Roentgenographic examination also provides information about the presence of such complications as empyema, atelectasis and purulent pericarditis.

**Laboratory Data.** Except in complicated cases there is usually not more than a slight reduction in the red blood cell count and the hemoglobin. The white blood cell count is usually increased to 15,000 to 40,000 per cubic millimeter, with a preponderance of polymorphonuclear cells. White blood cell counts below 5000 per cubic millimeter, as well as excessively high counts of 50,000 to 100,000, are often associated with a grave prognosis.

The urine is usually highly colored, of high specific gravity, scanty in amount, and loaded with urates. There is usually a moderate albuminuria and a few hyaline casts. Acetonuria is common.

The *Pneumococcus* can be isolated from nasopharyngeal secretions in most instances. Typing at present has little practical value, since specific antisera are rarely used in therapy. Positive blood cultures are obtained in about 10 to 20 per cent of all cases of pneumococcal pneumonia. Bacteremia is more frequent in infections with types I, II and III than in infections with the higher-numbered types.

**Differential Diagnosis.** The principal conditions from which bronchopneumonia must be differentiated are severe acute bronchitis, acute bronchiolitis, chronic passive congestion in cardiac failure, acute exacerbations of bronchiectasis, patchy areas of atelectasis, and pulmonary tuberculosis.

Lobar pneumonia must be differentiated principally from massive atelectasis and pleural effusion, and from meningitis, gastroenteritis and appendicitis when symptoms arising from a pneumonic infection simulate one of these conditions. Tuberculosis and bronchiectasis are less likely to be confused with lobar pneumonia than with bronchopneumonia, although each of these conditions may be responsible for collapse or consolidation of an entire lobe.

**Complications.** Some degree of *plastic pleurisy* is present in nearly all cases of pneumonia; small amounts of serous effusion are common and can scarcely be considered complications. In the presulfonamide era *empyema* developed in about 5 to 10 per cent of cases. It is the most characteristic complication of pneumonia, but it is now uncommon

in cases treated early. Spontaneous pneumothorax is a rare complication. *Otitis media* was also a common complication, especially in infants and young children, but its incidence has also been reduced by antibacterial treatment. Purulent pericarditis, peritonitis and meningitis are infrequent complications. Both pneumococcal meningitis and pneumococcal peritonitis occur more frequently without a coexisting pneumonia than they do with it. Endocarditis, encephalitis, parotitis, nephritis, osteomyelitis, subcutaneous emphysema and pulmonary abscess are rare complications. Hemiplegia and other localized brain lesions have been recorded and have been attributed to thrombi and emboli. Atelectasis is an occasional complication, and it is not unlikely that a number of so-called unresolved pneumonias are actually areas of atelectasis. When atelectasis persists, there is always danger that bronchiectasis will develop. Bullous emphysematous blebs (Fig. 222; p. 807) may simulate an abscess cavity, but are usually benign and spontaneously corrected.

One of the most serious complications of pneumonia has been *abdominal distention* or *tympanites*, which, when persistent, is usually a reflection of paralytic ileus. It is now rare except in untreated infants and young children.

**Prognosis.** Both the course and the outcome of pneumococcal pneumonias have been dramatically changed by treatment with sulfonamides and antibiotics. Before effective drugs or type-specific antiserum was available the mortality in the first two or three years of life, and especially in the first, ranged from 20 to 50 per cent. In contrast, the fatality rates for the remaining years of childhood were extremely low, being only 3 to 5 per cent. When treatment is instituted early in the course of the disease, fatality rates of less than 1 per cent may be expected in both infants and children.

It is unusual when the temperature does not return to normal within twenty-four hours after the institution of adequate therapy. Simultaneously there is improvement in the clinical condition of the child, and significant complications have been virtually eliminated.

**Treatment.** The favorable response to sulfonamide and/or antibiotic therapy and the decreased need for oxygen administration when chemotherapy is instituted shortly after the onset make home care of the pneumonic patient more feasible than it was in the past. There are certain advantages in keeping a child at home, including the psychologic ef-

fect of remaining in familiar surroundings and avoidance of the trip to the hospital. Keeping the child at home depends upon the physical adequacy of the home and upon the ability of the mother or other members of the family to supply good nursing care. The development of serious complications will necessitate removal of the child to the hospital.

Nursing and medical attention are essential, and should be designed to conserve the child's energy. The child's position in bed should be changed at frequent intervals to avoid discomfort and to facilitate drainage from the tracheobronchial tree. Dietary management in the average case of pneumonia is not particularly important other than avoidance of forcing the child to eat more than he desires. Under ordinary circumstances adequate amounts of fluids to supply the increased demands of the infection will be taken, if offered. However, when there is vomiting, fluids must be supplied by parenteral means. A fluid intake of sufficient quantity to maintain an output of urine of average specific gravity is important for the excretion of toxic products and is essential to avoid renal complications during the administration of sulfonamides.

Antibacterial therapy instituted at the earliest sign of pneumonia is the most important aspect of therapy. Fortunately the *Pneumococcus* is susceptible to practically all the

FIG. 222. Bullous emphysema in left lung field. This huge emphysematous bleb developed after a pneumonic infection. Its course was marked by decrease in size in all directions until it completely disappeared.

available antibiotics and the sulfonamides, except the poorly absorbed ones. Penicillin in full dosage would appear to be the drug of choice. It can be given orally at intervals of eight hours, or the aqueous preparation can be injected parenterally at intervals of eight hours, or procaine penicillin at intervals of twelve or twenty-four hours (see p. 222 for doses of penicillin, other antibiotics and the sulfonamides). The administration of the antibacterial agent should be continued for four or five days after the temperature is normal.

Administration of oxygen may be a life-saving measure when there is severe dyspnea, with or without cyanosis. The early administration of oxygen will greatly reduce the need for sedatives and analgesics and is preferred for quieting the restless, pneumonic child. Often oxygen therapy for a day or so is all that is required and results in a much smoother convalescence. Sedatives and analgesics are rarely needed. Aspirin in doses of 60 mg. (1 grain) per year of age is perhaps the best drug for mild restlessness, and phenobarbital may be given in addition for sleeplessness.

Severe abdominal distention is a serious complication for which prophylaxis is infinitely more effective than treatment. Prophylaxis consists in early antibacterial treatment of the pneumonic infection, administration of oxygen before extreme cyanosis is present, and avoidance of constipation. When there is an extreme degree of distention, treatment is rarely effective. For this reason Prostigmin, which is the most effective therapeutic agent, should be administered for moderate distention, especially when it is not relieved by an enema. Subcutaneous doses of 0.5 to 1 cc. of a 1:4000 solution may be given to infants one to two years of age, and may be repeated in two or three hours if the distention is not relieved. Enemas, with a rectal tube left in place, should be given in addition.

**Convalescence.** Recovery from uncomplicated pneumonia is usually rapid, but a common mistake is failure to provide for an adequate convalescent period because of the child's apparent well-being following antibacterial therapy. The test of completion of the convalescent period or the return to a healthy status is based on the regaining of the pre-illness weight, a sense of well-being and absence of fatigue after average daily activity. In general, the average child requires ten to fourteen days after defervescence for completion of convalescence.

### STREPTOCOCCAL PNEUMONIA

Pneumonic infections caused by the hemolytic streptococcus are in most instances secondary and follow such infections as measles, pertussis, influenza and the common cold.

The pathologic lesion is frequently that of a bronchitis and interstitial pneumonia with an infiltrate of mononuclear cells in the walls of the bronchi and bronchioles, which extends into the interalveolar septums. In some instances the lesion produced is a hemorrhagic pneumonia. The distribution is usually lobular, with consolidation of the alveoli, although, when the distribution is extensive, especially in one particular lobe, the confluent lobules may create the appearance of a lobar pneumonia. Subpleural abscesses and empyema are frequent manifestations.

The *clinical course* of streptococcal pneumonia is usually that considered characteristic of bronchopneumonia. Immediately or shortly after the acute phase of some infection which involves the upper respiratory tract, there is an elevation of temperature, dyspnea and cough. The fever is remittent, and as a rule the infant or child is quite sick. The *physical signs* vary considerably, but often there is nothing more than scattered areas of rales with percussion dullness over the larger of these areas. The *diagnosis* is established by demonstration of pneumonic areas on the roentgenogram of the chest and by identification of the organism from cultures of nasopharyngeal secretions. Empyema is a frequent complication, except as treatment is instituted early.

The *prognosis* has been improved tremendously by antibacterial therapy. The general *treatment* is that described for pneumococcal pneumonia.

### STAPHYLOCOCCAL PNEUMONIA

Within recent years the *Staphylococcus aureus* has become the most important pulmonary bacterial pathogen encountered in pediatric practice. This changed situation is principally the result of two factors: the effective control of most other bacterial pneumonias by antimicrobial agents and the emergence of virulent, antibiotic-resistant staphylococci. The problem is largely centered in infancy, many of the pneumonic infections being acquired in hospital nurseries. The epidemiologic aspects extend beyond the nursery, however, and infections may be acquired at home, in hospital wards and in other institutions. Frequently the newborn infant acquires

skin infections in the nursery and/or becomes a carrier of virulent staphylococci in his nasopharynx. From such sources he may transmit the infection to other members of the family and may himself have a more serious staphylococcal infection, such as pneumonia, weeks or months later. The infection in the newborn period is discussed on pages 328 and 344. The Staphylococcus is also a common pulmonary pathogen in children with fibrocystic disease of the pancreas.

The onset and progression of pneumonic lesions tend to be extremely rapid. There may be a single lesion, but more often there are multiple lesions. Destruction of tissue and abscess formation are the typical pattern. Lesions near the periphery often erode into the pleura, producing tension pneumothorax and/or empyema. A roentgenogram of the chest will often give a clue to the diagnosis by the demonstration of multiple lesions which after a day or so may be suggestive of abscess formation. Nasopharyngeal cultures will usually reveal the organism, and the blood culture is frequently positive.

The case fatality rate approximated 100 per cent in infants prior to the introduction of sulfonamide and antibiotic therapy. For a few years thereafter infections were largely controlled. But, as stated above, the situation is again critical, and no completely adequate solution is at hand.

Prophylactic measures to control nursery infections are described on page 345; the principles of treatment on pages 345 and 431. It is essential that the possibility of staphylococcal pneumonia be considered initially in every instance of pneumonia in infants and young children. Nasopharyngeal and blood cultures should be obtained immediately, the patient isolated in an area where he may have constant and close nursing supervision, and antimicrobial therapy started immediately. When the possibility of staphylococcal pneumonia seems especially likely, two antibiotics, each known to be effective against a fair number of strains, should be prescribed in full dosage. No antibiotic is known to be effective against all strains; those which have the widest range of effectiveness include chloramphenicol, erythromycin, novobiocin, oleandomycin and kanamycin. The initial prescription should be altered as indicated by the result of sensitivity tests in the bacterial culture and by clinical response. The infant must be watched closely for the possible development of tension pneumothorax (p. 817) and/or empyema (p. 815). General

supportive treatment is also of great importance; this includes oxygen therapy, maintenance of fluid and electrolyte balance and scrupulous nursing care.

#### HEMOPHILUS INFLUENZAE PNEUMONIA

The epidemiology of influenzal bacillus infections is not clearly understood; whereas *H. influenzae* type b is a common cause of meningitis in infants, it is an infrequent cause of primary pneumonia. Clinically, it would seem probable that many of the pulmonary infections are mixed ones, the resultant pathologic changes being due to the synergistic action of the influenzal bacillus with some other bacterium such as the Pneumococcus or the Streptococcus or one of the viral agents, or that the influenzal infection is superimposed upon a preceding infection. Blake and Cecil, however, produced pulmonary lesions in monkeys with pure cultures of *H. influenzae* type b which are quite similar to those observed by Trask and others in man. The characteristic lesion consists in destruction of the mucosa and submucosa of the bronchi and bronchioles, resulting in a bronchiolitis and interstitial pneumonitis and a hemorrhagic edema. Practically all infections in man appear to be caused by the type b group of *H. influenzae*. It has been considered one of the etiologic agents of acute laryngotracheobronchitis and acute bronchiolitis and less often of lobar or segmental pneumonia (Nyhán). In this last instance the infection may simulate pneumococcal pneumonia, and empyema may be a complication. Type a *H. influenzae* has also been associated with acute bronchiolitis. The importance of blood cultures in the evaluation of all patients with pneumonia is especially evident in *H. influenzae* type b pneumonia, in which a positive culture is the only certain diagnostic means, except when empyema is associated and a positive culture is obtained from the pleural fluid. The child should be observed for the development of meningitis.

Treatment consists in symptomatic and supportive measures appropriate for pneumonia and in antibacterial therapy effective against the *H. influenzae*. An effective plan is the administration of sulfadiazine and chloramphenicol in combination. Streptomycin is also effective.

#### FRIEDLÄNDER'S BACILLUS PNEUMONIA

Friedländer's bacillus is an uncommon cause of pneumonia at any age, and an especially infrequent one during infancy and childhood.

The infection may be primary or secondary. The characteristic distribution of the lesions is lobar or confluent lobular, and one or more lobes may be involved. There is a tendency to abscess formation. In the acute cases the onset is abrupt, and the general symptoms are those of bronchopneumonia. Hematemesis and melena may be observed in infants and children. The most frequent complications are extensive abscess formation and empyema; other less common ones are pericarditis, meningitis and arthritis. Streptomycin or chloramphenicol in combination with a sulfonamide appears to be as effective as any available therapy.

## VIRAL OR PROBABLY VIRAL INFECTIONS

### ACUTE BRONCHIOLITIS AND INTERSTITIAL PNEUMONITIS

(VIRUS PNEUMONIA, VIRAL PNEUMONITIS OF INFANTS, CAPILLARY BRONCHITIS)

The terms "acute bronchiolitis" and "acute interstitial pneumonitis" are used more or less interchangeably, especially in pulmonary in-

fections in infants and very young children. Perhaps bronchiolitis might be considered a more appropriate clinical diagnostic term, but it is difficult to conceive of the existence of a pure bronchiolitis without involvement of the interstitial tissues.

The clinical pattern of acute bronchiolitis is seen with frequency only in the first two years of life, and the majority of infections occur in the first six months. It may be that infections of this type actually occur more frequently in this age group than in older children and adults, but there is some reason to doubt whether this is the sole explanation. There may be anatomic differences in the pulmonary trees of infants and older children that are responsible for variations in clinical patterns or the responses to the same etiologic agents (see Primary Atypical Pneumonia).

**Etiology.** No single etiologic agent is responsible for this disease. Failure to isolate any of the usual pathogenic organisms of the respiratory tract in a significant number of instances and the failure of the disease to be affected by sulfonamide or antibiotic therapy have been responsible for the belief that a virus is the usual etiologic agent. Certain viruses and rickettsiae (the viruses of influenza, psittacosis, ornithosis, lymphogranuloma venereum, lymphocytic choriomeningitis and the rickettsia of Q fever), some of which respond to sulfonamides and/or antibiotics, may be responsible for bronchiolitis and interstitial pneumonitis, but in the main the viral agents are not known. It may be that some of them are responsible for acute upper respiratory tract infections in the majority of instances, especially in older children and adults. Adams reported several epidemics of primary viral pneumonitis among full term and premature newborn infants when the onset of the pneumonia was within the first twenty-four hours of life and the mother had an acute upper respiratory tract infection. There is some evidence to indicate that so-called Streptococcus MG and *H. influenzae* (both types a and b) may be occasional causative agents. Adams presented data suggestive of a possible relation between the etiologic agent of primary viral pneumonitis in infants and that of distemper in dogs.

**Epidemiology.** The incidence of acute bronchiolitis is highest in the winter and early spring months. Most infections occur sporadically, but an increased number of cases in infants often coincides with epidemics of upper respiratory tract infections among older children and adults. There are

no known sex or race differences, and nutritional status does not appear to be a factor.

**Pathology.** The lungs are emphysematous with scattered areas of atelectasis. Histologically, the most striking changes are in the walls of the bronchi and bronchioles, which are thickened by an infiltrate of small lymphocytes, plasma cells and scattered neutrophils; these lumina contain mucus and varying amounts of neutrophilic exudate. The inter-alveolar septums about the bronchioles are thickened as a result of an inflammatory infiltrate similar to that present in the bronchiolar walls. Intra-alveolar exudate is usually minimal unless secondary infection has occurred.

**Clinical Manifestations.** The description which follows applies to the infection in infants and young children. The description of similar infections in older children is given under Primary Atypical Pneumonia.

The onset of bronchiolitis usually follows that of an upper respiratory tract infection by two or three days and is characterized principally by a dry, persistent cough and increasing dyspnea. The clinical pattern varies in severity and to a less extent in the manifestations themselves. In atypical cases the cough may so closely simulate that of pertussis that differentiation can be made with certainty only by bacteriologic cultures, although the nature of the disease may be suggested by the white blood cell count. Initially, the respiratory symptoms are more marked than those of toxicity, and the clinical pattern is suggestive of bronchial asthma. The temperature is extremely variable, but most often there is only a slight elevation to 100° or 101° F. Most important is the fact that there is no correlation of the clinical severity with the temperature elevation. Vomiting may occur, but it is usually not a serious problem, nor is severe diarrhea. Feeding, however, may present difficulties, because sucking is interrupted by the dyspnea, and the distention of the thoracic cavity compresses the abdomen.

On physical examination the infant is found to be alert, apprehensive and exceedingly irritable. The respirations are rapid and shallow and often accompanied by an expiratory grunt. The accessory muscles of respiration are used actively so that there is suprasternal and subcostal indrawing with inspiration, but the depth is not as great as in laryngeal obstruction, owing to distention of the lungs. The physical findings in the severe case are those of generalized obstructive emphysema (see pp. 775 and 806).

Cyanosis may be marked, and often there is extreme pallor. The percussion note is hyperresonant; there may be no rales, or there may be widely scattered fine or medium ones. Wheezing may be prominent and accompanied by sibilant and musical sounds. When bronchiolitic obstruction is nearly complete in the most severe cases, the breath sounds may barely be audible.

Dehydration may be relatively severe, owing to the excessive loss of water through hyperventilation. Death may be due to exhaustion from respiratory effort or to cardiac failure.

**Diagnosis.** The roentgenographic and fluoroscopic examinations reveal generalized obstructive emphysema of varying degree (see p. 806) with or without evidence of scattered parenchymal infiltration.

The white blood cell count is usually not significantly altered. Nasopharyngeal cultures as a rule do not reveal significant deviations from the usual flora. There may be respiratory acidosis.

The differential diagnosis in the main includes those diseases which also cause generalized obstructive emphysema, and particularly those which have an acute onset. Thus asthma is simulated most closely; it does occur in infants, but is relatively uncommon at this age. Cystic fibrosis of the pancreas, the onset of miliary tuberculosis, pertussis (cough), aspiration of zinc stearate or other irritant substances, silicate poisoning (hyperpnea) and endocardial fibroelastosis must also be considered.

**Prognosis.** Though there is no specific therapy, a favorable outcome can be expected in most instances, even in the more severe cases, if adequate supportive therapy is provided. There are no adequate case fatality data, but the rate is probably less than 5 per cent. In newborn infants, and especially in premature ones, it may be higher. Adams observed case fatality rates of 28 and 14 per cent, respectively, in two of three epidemics.

Complications include bacterial bronchopneumonia, otitis media, pulmonary atelectasis and abscess and cardiac failure. Permanent sequels are extremely rare.

**Treatment.** The treatment is symptomatic. All infants with bronchiolitis should be placed in an atmosphere of high humidity, preferably with cold vapor rather than steam. Those with even moderately severe dyspnea should also receive oxygen therapy; one should not wait for the development of cyanosis. The infant is usually more comfortable if the head

and chest are slightly elevated. The dehydrating effects of the dyspnea should be combated by ample oral intake of fluids or, when this is not adequate, by parenteral administration of water and glucose. No concern need be felt if the caloric intake is not adequate during the few days of the acute phase, and the infant should be permitted to eat as he desires. Generous amounts of the water-soluble vitamins should be provided.

Although antibiotic therapy has not been effective in many instances of bronchiolitic infections, broad-spectrum coverage (p. 208) is indicated for severely ill infants since an occasional case has seemed to have been benefited. The experience with corticosteroids does not indicate any significant effect. When they are used, it is obligatory that broad-spectrum antibiotic therapy also be provided.

When there is considerable accumulation of exudate in the tracheobronchial tree and/or when there is atelectasis, bronchoscopic aspiration may be beneficial.

#### PRIMARY ATYPICAL PNEUMONIA, ETIOLOGY UNKNOWN

This diagnostic term is used for a respiratory infection characterized by a more or less acute onset with fever, malaise, persistent and distressing cough, and as a rule little dyspnea, at least in older children and adults. The roentgenographic evidence of pneumonic involvement is characteristic in its distribution and out of proportion to the physical signs, which may even be absent.

**Etiology.** Present evidence suggests that a variety of viral agents may be responsible for the syndrome (see p. 794). There are also some data indicating that *Streptococcus MG* may have an etiologic role.

**Epidemiology.** All ages are apparently susceptible, though no accurate data are available. The disease is apparently not limited in its geographic distribution. Epidemics may occur, but the disease is endemic, and cases are observed throughout the year.

**Pathology.** The following description is from Golden:

The weight of the lungs is average or only moderately increased. The pleural surfaces are smooth or glistening with occasional patches of frank fibrinous exudate. In a few instances there were small pleural effusions of an amber colored fluid. The parenchymal distribution varied from a portion of one lobe to a diffuse bilateral involvement. The focal lesion grossly resembled a miliary granuloma. However, these whitish nodules were found to be thickened bronchiolar walls from which frank pus exuded. The immediately surrounding pulmonary tissue was

either spongy and grossly normal or at times edematous, hemorrhagic, and congested. The mucous membrane of the large branches of the tracheobronchial tree either appeared normal or slightly edematous and congested; rarely was it acutely inflamed or ulcerated. The principal lesions appeared to be in the bronchioles where, in focally distributed lesions, there was desquamation of the mucosal surfaces. The lumens contained frank pus, mucoid fluid, and desquamated epithelial cells. Bacteria were not commonly present and there was no consistency in the types of those found. The bronchioles were markedly dilated and their walls were infiltrated with cells which were chiefly mononuclears. This cellular infiltration radiated into the regional interstitial tissues, the alveolar walls, and the pulmonary septums. The alveoli either contained air or were collapsed, but were free of exudate. Evidences of pneumonia were present when there was secondary bacterial invasion.

**Clinical Manifestations.** The incubation period has been estimated to be from ten to twenty-one days; by experimental inoculation (throat spray) it is seven to fourteen days (Dingle). The onset is usually gradual; initially for a few days there is malaise and a slight cough, then an elevation in temperature which may range from 101° to 105° F., but usually is not more than 103° F. The cough becomes more severe and is usually the most troublesome symptom; it is often paroxysmal, and in children may simulate that of pertussis so closely that this disease may be suspected. The cough is dry, and there is no sputum during the initial stage, but it is often present in the later stage of the illness and may become blood-streaked.

The *older child* does not as a rule appear to be as ill as his fever would indicate. The respiratory and pulse rates are usually only slightly increased. Severe degrees of dyspnea are uncommon, and cyanosis is rare. The throat may be mildly injected, and there may be slight enlargement of the cervical lymph nodes. The paucity of abnormal findings is striking; often there is none at all. Rales are occasionally heard in isolated areas, and infrequently there are isolated areas of dullness, usually with diminished breath sounds. Evidences of extensive consolidation, of friction rubs and of pleural fluid are rare. Meningismus has been noted in a few instances.

There is little information about the clinical pattern of primary atypical pneumonia in infants, but there is presumptive evidence that some of the cases of bronchiolitis may belong in this category (p. 794).

The roentgenogram usually shows changes out of proportion to the physical findings. Characteristically, there are evidences of in-

filtration which extend from the hilar regions and branch out as they approach the periphery (Fig. 223), or there may be diffuse nodular areas. The lesions may be confined to one lobe, more commonly a lower one, or may be present in several or all lobes. There may be widespread, generalized obstructive emphysema, especially in infants.

**Laboratory Data.** The white blood cell count is rarely significantly altered; it may be slightly increased or decreased. Total counts below 4000 or above 15,000 per cubic millimeter are unusual. The erythrocyte sedimentation rate is usually increased, and the increased rate often persists for several weeks into the convalescent phase. The urine shows no consistent abnormalities.

In many cases of primary atypical pneumonia of unknown etiology cold agglutinins against group O human erythrocytes develop in high titer. They usually appear during the second week after the onset of fever and persist for several weeks. Significant titers of cold agglutinins are rarely encountered in bacterial pneumonias and in other acute respiratory infections. Agglutinins to *Streptococcus MG* are also observed after primary atypical pneumonia with a frequency about equal to that of cold agglutinins. Temporary, falsely positive serologic tests for syphilis are also occasionally noted.

**Differential Diagnosis.** *Pneumonias* resulting from infection with the common as well as the unusual bacterial agents must be excluded by bacteriologic means. The principal confusion is likely to be with *influenzal virus infections*; cold agglutinins are rarely found in association with this infection. During the acute stage the possibility of tuberculosis must also be considered, but is readily eliminated by the natural course of the infection. At present the diagnosis of primary atypical pneumonia is made by exclusion of other diseases, by the more or less characteristic roentgenographic pattern, by the subsequent appearance of cold agglutinins or of agglutinins to *Streptococcus MG*, and by failure of the patient to respond to antibacterial therapy.

**Complications.** In contrast to the bacterial pneumonias, complications are uncommon. Occasional instances of recurrence have been recorded. Otitis media occurs at times; empyema, pneumothorax and bronchiectasis are rare complications.

**Course and Prognosis.** The course of the acute phase averages about eight to ten days, but shorter or longer periods are common.

Roentgenographic evidence of the pulmonary lesion may persist for several weeks. The child should be permitted a convalescent period at least equal to that of the acute phase, and a longer period if the usual strength and vigor have not been regained.

The prognosis for complete recovery is good in children beyond the age of infancy, the case fatality rate being less than 1 per cent. (For infants, see p. 795.)

**Treatment.** Treatment is symptomatic. The child is usually more comfortable in an atmosphere of high humidity; for this purpose cold vapor is preferable to the steam inhalator. Phenobarbital may be required to secure adequate rest for the child because of the coughing. No antibacterial therapy is indicated in older children; for infants, see treatment of bronchiolitis. Secondary bacterial infections should be treated with appropriate antibacterial agents.

### GIANT CELL PNEUMONIA

Giant cell pneumonia (Hecht) is a subacute or chronic interstitial pneumonitis occurring in infants and young children. Clinically, it is indistinguishable from other subacute or chronic pneumonitides. Pathologically, it is characterized by the presence of multinucleated giant cells containing intranuclear and

FIG. 223. Primary atypical pneumonia. Extensive changes throughout most of the right lung and base of left lung. There is more abnormality in the left lower lobe than appears on the roentgenogram, because much of it is hidden behind the heart.

intracytoplasmic inclusion bodies; it seems probable that demonstrations of such giant cells in the sputum might be of value in the antemortem diagnosis of the disease. The etiology has not been established, but the similarity of the lesions to those of distemper in animals and the frequent association with measles strongly suggest a viral origin.

#### PLASMA CELL PNEUMONIA

This pneumonic involvement, which is now considered by some observers to be a primary disturbance, appears to be limited to infants of one to four or six months of age and occurs principally in premature and debilitated full term ones. The geographic distribution is of equal interest; it has been observed with any degree of frequency only in the central and northern European countries, and a few cases have been described in the United States within the past few years.

The etiology is not definitely known, but the protozoan, *Pneumocytis carinii*, initially observed in the alveolar exudate by Vaněk and co-workers, has now been identified in tissue sections by a number of other investigators.

On examination the lungs are typically pale gray to gray-blue in appearance and do not collapse. Only the anterior portions of the lung have any significant amount of air-bearing alveoli, where there may be some obstructive emphysema. Histologically, the septums are widened, and the alveoli are mostly collapsed or filled with exudate. The cellular infiltrate is composed almost entirely of mononuclear cells, which resemble plasma cells, histiocytes and intermediary forms.

Clinically, the onset is slow and insidious, in some instances being preceded by an upper respiratory tract infection or diarrhea by several days or weeks. The incubation period has been estimated to be twenty to sixty days. Initially, there is nothing to direct attention to the pulmonary involvement. The infant becomes apathetic, loses his appetite and either fails to gain or loses weight. Then within a week or two his respirations begin to increase in rapidity. This tachypnea is considered the most characteristic sign; the rate may be 80 to 120 per minute. Cough and fever are not prominent, but as the disease progresses the infant becomes cyanotic, often exhibiting a grayish cast of the skin.

The physical examination is not characteristic. There may be scattered areas of impaired resonance and suppressed breath sounds, and often widely scattered fine rales.

Emphysema is a common complication; presumably starting interstitially, it may be responsible for pneumomediastinum, pneumothorax and subcutaneous emphysema. The white blood cell count may be increased up to 20,000 per cubic millimeter. Roentgenographically, there are scattered small infiltrative areas and at times larger ones.

The course is prolonged in the nonfatal cases, from four to six weeks. The case fatality rate is not known, but has been estimated to be from 20 to 50 per cent.

There is no known specific treatment.

#### THRUSH PNEUMONIA

Oral infections with *Candida albicans* are discussed on page 633, and the occasional complication of an esophagogastritis is mentioned. Adams reported seven cases of pneumonia in infants with oral thrush. The presence of

pneumonia was confirmed by roentgenographic examination. Death occurred in one infant, and the autopsy revealed a widespread staphylococcal pneumonia with multiple small abscesses. A synergistic action between *C. albicans* and a strain of *Staphylococcus* was postulated.

#### ASPIRATION PNEUMONIAS

For Fetal Anoxia with Aspiration of Excessive Amniotic Debris, see page 321.

#### ASPIRATION OF FOOD

Infants with obstructive lesions, such as tracheo-esophageal fistula and duodenal obstruction, and weak and debilitated infants who have no obstructive lesions may aspirate, or regurgitate and then aspirate, a sufficient amount of food to cause significant mechanical damage. At times it is an immediate cause of death by asphyxiation. In other instances the irritated mucous membrane becomes a site for bacterial invasion. Prophylaxis is of the greatest importance. Care should be taken to avoid amounts of feedings that will overdistend the stomach; this is especially true for infants whose feeding is gavage. After the infant has been fed he should be placed on his abdomen or on his right side. When in the supine position, care should be taken to see that his head is not lower than the rest of his body. Drainage from the lungs may, however, be materially aided by lowering the head of the bed while the infant is lying on his abdomen.

#### ASPIRATION OF ZINC STEARATE

Aspiration pneumonia resulting from inhalation of zinc stearate powder, once relatively common, has now become comparatively rare because of efforts directed against the use of this powder for infants. The containers have also been equipped with an automatic closing device, but this is not infallible. Severe respiratory distress follows inhalation almost immediately. There is a generalized obstructive emphysema with an expiratory type of dyspnea. In the severe cases dyspnea and cyanosis persist in spite of oxygen therapy. The embarrassment to respiration appears to be the result of two factors, a mechanical obstruction and an inflammatory reaction caused by the irritation of the zinc stearate.

Owing to the extreme lightness of the powder it is almost immediately drawn into the finer bronchioles, and for this reason bronchoscopic aspiration is of little avail except to remove the secretions which subsequently accumulate. If the child survives the acute episode, he is especially liable to bronchopneumonic infections.

Immediate *treatment* consists in oxygen therapy in an atmosphere of high humidity. Bronchoscopic aspiration is indicated when there is an excessive accumulation of secretions in the larger air passages. If the infant survives the mechanical phase, an antibacterial agent should be prescribed for prophylactic purposes.

#### ASPIRATION OF DUST

A type of bronchitis has been described which is associated with prolonged exposure to high concentrations of dust. In a reported instance the source of the dust was a large clay playground. The complaints are an uncomfortable tickling sensation in the throat and an explosive, intractable, nonproductive cough. The only abnormal physical signs are rhonchi and some wheezing sounds. The cough persists for ten to fourteen days. Roentgenograms of the chest show a soft patchy mottling with increased bronchovascular markings, usually in the lower lobes.

*Treatment* is symptomatic and should include humidification during the stage of irritation. The prevention of dust dispersion is accomplished by frequent wetting of the soil, by utilization of some binder such as calcium chloride, or by asphaltting the surface.

#### KEROSENE PNEUMONIA

Pulmonary disturbances are frequently associated with the accidental ingestion of kerosene. (See Hydrocarbons, page 1388, for other manifestations of kerosene poisoning.)

There are conflicting interpretations of the *pathogenesis* of the pulmonary lesions. Some investigators contend that most of the kerosene reaches the lungs after absorption from the gastrointestinal tract, whereas others believe that aspiration during swallowing, vomiting or gastric lavage provides the principal means for pulmonary contamination. Consequently there are divergent views concerning the advisability of gastric lavage after the ingestion of kerosene or other hydrocarbons. The pulmonary changes observed in animals are edema, inflammation and hemorrhage.

Coughing and vomiting follow ingestion almost immediately. There is an elevation of

temperature (100° to 104° F.), and the child may be drowsy or comatose. The pulmonary findings are diminished resonance on percussion, suppressed or tubular breath sounds, and rales. The presence of pneumonic involvement is disclosed more frequently by roentgenographic examination than by physical findings. Pleural effusion, which may become purulent, pneumothorax, and subcutaneous emphysema of the chest wall have occurred as *complications*. In spite of the stormy clinical course, which averages two to five days, recovery occurs in most instances.

*Treatment* is symptomatic. An antibiotic should be administered prophylactically, or therapeutically if a secondary infection has occurred. When only small amounts of kerosene have been ingested, and especially if several hours have elapsed, gastric lavage probably should be omitted. When large quantities of kerosene or other hydrocarbons have been ingested, lavage should be performed with great care to avoid aspiration. In either instance a saline cathartic should be administered. If there is dyspnea or cyanosis, the child should be placed in an oxygen tent.

#### LIPOID PNEUMONIA

Lipoid pneumonia is a chronic, interstitial, proliferative inflammation resulting from aspiration of lipid material; it occurs principally in debilitated infants.

The factors which may be responsible for aspiration of oil include (1) intranasal instillation of medicated oils, (2) any condition which interferes with the swallowing act, such as cleft palate, debilitation, and an enforced horizontal position during feeding, and (3) forced feeding and especially the administration of cod liver oil, castor oil or mineral oil to crying children.

The severity of the pulmonary reaction depends upon the type of oil inhaled. Vegetable oils as a group are the least irritating; such oils as olive, cottonseed and sesame produce no inflammation; chaulmoogra, a vegetable oil, on the other hand, is responsible for extensive damage. Animal oils, owing to their high fatty acid content, are the most damaging. Cod liver oil belongs in this category. Liquid petrolatum is chemically inert and is not so irritative as some of the other oils, but does act as a foreign body.

Initially, the reaction within the lung is essentially an interstitial proliferative inflammation with which there may be an exudative pneumonia. In the second stage there

FIG. 224. Roentgenogram showing increased density radiating from the hilum of each lung in an infant 13 months of age after intranasal application of liquid petrolatum 3 times a day for 5 months.

is diffuse, chronic, proliferative fibrosis. Acute bronchopneumonia is not infrequently superimposed in this stage. In the third stage there are multiple localized nodules, the so-called tumor-like paraffinomas. Microscopically there are numerous macrophages in the involved areas with giant cell formation of the foreign body type. The lipid substance is both intracellular and extracellular. The oil-laden cells may be carried through the lymphatic channels to the hilar lymph nodes.

**Clinical Manifestations.** There are no characteristic signs or symptoms. The most common symptom is cough, and in severe cases there may be dyspnea. Unless there is a superimposed infection, there are usually no fever and no physical signs. With extensive involvement there may be some impairment to percussion and increased or decreased voice and breath sounds. Secondary bronchopneumonic infections are common.

The only characteristic finding is the roentgenographic appearance. When there is only a mild involvement, there is an increase both in the degree of density and the extent of the hilar shadows. With increasing involvement there is greater density of the perihilar shadows with widening in all directions (Fig. 224). In a few instances the pulmonary changes have been limited to the right lung, and, in the infant who is recumbent most of the time, the changes may be largely in the right upper lobe.

**Prognosis.** The prognosis is guarded. It depends upon the extent of pulmonary damage, the discontinuance of oil inhalation, the general condition of the infant, and the avoidance of intercurrent infections.

**Prevention.** Intranasal medication in an

oily vehicle should never be used. Concentrated preparations of vitamins A and D in water-miscible vehicles should be substituted for cod liver oil. Administration of mineral oil and castor oil should be avoided. Infants who regurgitate or vomit frequently should be placed on their abdomens to lessen the likelihood of aspiration.

**Treatment.** There is no specific treatment. The administration of oil should obviously be discontinued. The infant's position should be changed frequently to lessen the chances of hypostatic pneumonia. Efforts should be made to avoid contact with infectious diseases.

## LÖFFLER'S SYNDROME

### (EOSINOPHILIC PNEUMONIA)

This condition is a clinical syndrome characterized by widespread, small, transitory pulmonary infiltrations which roentgenographically bear a resemblance to those of miliary tuberculosis, and by a blood eosinophilia which often is as high as 40 to 70 per cent. The *clinical course* is, as a rule, not particularly severe and varies from a few days to several months. Features more or less common to the reported cases are paroxysmal attacks of coughing, dyspnea, pleurisy and little or no fever. Zuelzer and others have called attention to the association of hepatomegaly in this syndrome, especially in infants and young children. Biopsy sections of the livers revealed multiple focal areas of necrosis, granuloma formation and eosinophilic infiltration. These children also had hyperglobulinemia, presumably as the result of hepatic dysfunction. Reported autopsy studies have revealed evidences of eosinophilic infiltrations in the lungs and in other organs. Instances have also been recorded of localized pneu-

monic consolidations with an eosinophilia as high as 22 per cent. There is some doubt whether Löffler's syndrome is a clinical entity, and the possibility has been suggested that it is merely an unusual allergic manifestation. Cat and dog ascarids have been shown to be a cause of this syndrome (p. 578); whether they are the sole cause is yet to be established.

## HYPOSTATIC PNEUMONIA

Hypostatic pneumonia occurs after prolonged passive pulmonary congestion and may occur in any marantic state. Lying for a long time in one position favors its development. The pathologic lesion consists in dependent congestion, edema and pneumonia.

**Clinical Manifestations.** The symptoms are not characteristic. There is neither dyspnea nor fever, unless these symptoms are dependent upon the primary disorder. The physical signs are principally slight dullness on percussion, feeble respiratory sounds, and the presence of moist rales. Hypostatic congestion is usually a terminal event.

**Treatment.** Treatment is that of the primary affection. Prophylaxis is of the greatest importance; the position of the patient should be frequently changed when there is a possibility of development of passive pulmonary congestion.

## IDIOPATHIC PULMONARY

### HEMOSIDEROSIS

#### (ESSENTIAL BROWN INDURATION OF THE LUNGS)

Idiopathic pulmonary hemosiderosis is a rare condition in which the onset appears to be in childhood and the disease is largely limited to this age period. There does not appear to be a hereditary or familial factor. This condition is not part of a generalized hemosiderosis, nor is there any disturbance of iron metabolism as in hemochromatosis. Wyllie suggests

that the primary defect may be in the pulmonary interstitial tissue where capillary stasis results in hemorrhage by diapedesis and deposition of hemosiderin. Steiner has postulated an antigen-antibody reaction and reports improvement in a boy after splenectomy. *Pathologic changes* are limited to, or maximal in, the lesser circulation. Myocardial changes are insufficient to account for the pulmonary lesions. Anemia, when present, appears to be secondary; in some instances there is a compensatory rise in the red blood cell count in association with cyanosis in the final stages of the disease. Secondary inflammatory changes in the lungs are not common.

Characteristically there are recurrent attacks, often sudden in onset, of fatigue, cyanosis, pallor, dyspnea and accelerated pulse rate. Cough is troublesome, often followed by vomiting, and there may be small or large quantities of blood in the sputum or vomitus. Occult blood can also be demonstrated in the feces. Abdominal pain may be a feature, and the temperature may be elevated slightly or to as much as 103° F. at the height of the attack. The acute phase, which may be extremely severe, lasts two or three days and may be followed by a subacute phase. The clinical pattern of the acute phase is one of congestive cardiac failure. Pallor, jaundice, and enlargement of the liver and spleen may be features of the subacute phase, and clubbing of the fingers may develop. The *prognosis* is grave.

The *roentgenographic findings* are mottled shadows most noticeable in the hilar areas with a diffuse speckling throughout the lung fields, resembling somewhat the appearance of miliary tuberculosis.

*Hemosiderin* may be seen in macrophages in the sputum or in material obtained bronchoscopically or by gastric lavage.

#### ATELECTASIS

Congenital atelectasis is discussed on page 324.

#### ACQUIRED ATELECTASIS

**Etiology.** Atelectasis, imperfect expansion or collapse of the air-bearing tissue of the lung, is relatively common in infants and children. Collapse may be produced by any factor which completely obstructs the intake of air into the alveolar sacs and persists for a sufficient time to permit absorption of the existing alveolar air into the blood stream. In general, the causes may be divided into two groups: (1) external pressure directly upon the pulmonary parenchyma or a bronchus or bronchiole, and (2) intrabronchial or intrabronchiolar obstruction. Any factor responsible for a continuously decreased amplitude of respiratory excursion or for respiratory paralysis may be contributory. Reflex stimuli have also been considered initiating factors. De Takats demonstrated that at least three distinct stimuli, namely, pulmonary embolism, intra-abdominal manipulation and trauma to the chest wall, are capable of initiating bronchoconstriction and increased bronch secretion. Allergy may be responsible for atelectasis by spasm of the bronchial or bronchiolar musculature and/or by production of an exudate which occludes the lumen.

**Atelectasis from external pressure.** External factors may be operative in one of four ways: (1) interference with the movements of the thoracic cage (neuromuscular abnormalities as in cerebral palsy, poliomyelitis, amyotonia congenita, myasthenia gravis; osseous deformities as in rickets, scoliosis, kyphosis; scleroderma; splinting of the chest by casts and surgical dressings); (2) defective movement of the diaphragm (paralysis of phrenic nerve, increased abdominal pressure); (3) direct interference with expansion of lungs (pleural effusion, pneumothorax, intrathoracic tumors, diaphragmatic hernia); and (4) external compression of a bronchus completely obstructing ingress of air (enlarged lymph node, tumors, cardiac enlargement).

**Atelectasis from intrabronchial or intrabronchiolar obstruction.** (See also p. 774.) Complete intraluminal obstruction of a bronchus may be produced by a foreign body, by a neoplasm, by granulomatous tissue as in tuberculosis or by secretions as with bronchiectasis, pulmonary abscess or a tumor or allergy, chronic bronchitis or acute laryngotracheobronchitis.

Obstruction of one or more bronchioles in a given area may be produced by any of the conditions mentioned, but widespread bronchiolar obstruction is most often produced by

bronchiolitis or interstitial pneumonitis and by asthma. Generalized obstructive emphysema is the initial result of such bronchiolar obstructions; but as the pathologic changes progress, some of the bronchioles may become completely obstructed, and there are then interspersed small areas of atelectasis and emphysema. Patchy atelectasis is not frequent in acute bronchiolitis or in asthma, and is probably always present in advanced chronic diffuse infections such as the pulmonary infection associated with cystic fibrosis of the pancreas.

**Pathology.** The atelectatic areas are airless, congested, deep red, of a firm consistency, and depressed below the neighboring healthy or emphysematous lung. When there is extensive atelectasis of one or more lobes, there is usually compensatory emphysema of the air-bearing lung.

**Clinical Manifestations.** The symptoms vary with the cause and with the extent of the atelectasis. When only a small area is atelectatic, there are likely to be no symptoms referable to it. When a large area of the lung becomes atelectatic, and especially when it does so suddenly there is dyspnea with rapid shallow respirations, tachycardia, and often cyanosis. If the obstruction is removed, the symptoms disappear rapidly. Even atelectasis of an entire lobe may not be responsible for changes in the percussion note, owing to the compensatory emphysema of the adjacent

lung tissue. Breath and voice sounds are decreased or absent over extensive atelectatic areas.

**Diagnosis.** The diagnosis can usually be established by roentgenographic examination (Fig. 225). Small areas may be indistinguishable from pneumonic consolidations, but those that involve as much as several lobules of a lobe can usually be identified by the contraction of the area. When one or more lobes are atelectatic, the roentgenographic findings are those of massive collapse. Bronchoscopic examination will reveal a collapsed main bronchus when the obstruction is at the tracheobronchial junction and may also disclose the nature of the obstruction.

**Prognosis.** This depends upon the underlying cause. If the obstruction disappears spontaneously or is removed, the atelectasis usually disappears unless there is secondary infection. In the persistent cases bronchiectasis is a frequent complication and pulmonary abscess an occasional one.

**Treatment.** Bronchoscopic examination is indicated when an isolated area of atelectasis persists for several days, and immediately if it is the result of a foreign body or there is reason to believe that it is due to a bronchial obstruction which may be relieved. Frequent changes in the child's position and deep breathing may be beneficial. Oxygen therapy is indicated when there is dyspnea, and in all instances the child should be kept in an

FIG. 225. Atelectasis. The right upper lobe and the left lower lobe are collapsed. The atelectasis of the left lower lobe is demonstrated on the overpenetrated film (B). The atelectases occurred postoperatively and disappeared spontaneously.

FIG. 226. A, Massive atelectasis of the left lung, postoperative, with (B) comparison study after re-aeration of left lung. Onset of symptoms and signs occurred a few hours after appendectomy. Note the pneumoperitoneum, resulting from residual air when abdomen was closed. The heart and all other mediastinal structures have been drawn far to the left as a result of the atelectasis.

environment of high humidity (cold). Morphine and atropine are contraindicated.

#### MASSIVE PULMONARY ATELECTASIS

Massive collapse of one or both lungs is most often a postoperative complication, but occasionally results from other causes such as trauma, asthma, pneumonia, tension pneumothorax, the aspiration of foreign material (either a solid object large enough to obstruct the trachea or liquids such as water or blood) and paralysis such as that in diphtheria or poliomyelitis. Massive atelectasis is usually produced by a combination of factors: immobilization or decreased use of the diaphragm and the respiratory muscles, obstruction of the bronchial tree and abolition of the cough reflex. The Jacksons demonstrated that bronchial obstruction by thick secretions is present in a large percentage of postoperative cases and that prompt removal of it by bronchoscopic aspiration is successful in relieving the atelectasis.

**Clinical Manifestations.** The onset in postoperative cases is usually within twenty-four hours after operation, but may not appear for several days. There is dyspnea, cyanosis and tachycardia. The child is extremely anxious, there is likely to be prostration, and, if he is old enough, he usually complains of pain in the chest. The temperature may be as high as  $103^{\circ}$  or  $104^{\circ}$  F.

The physical signs are characteristic. The chest on the affected side appears flat, and there is decrease of respiratory excursion on that side. The intercostal spaces are narrowed, and there is dullness or flatness to percussion.

Breath and voice sounds are usually feeble or absent. The lower lobes are more frequently involved than the upper ones. The heart and mediastinum are displaced toward the affected side except in bilateral cases. Roentgenograms show the collapsed lung, elevation of the diaphragm, narrowing of the intercostal spaces and displacement of the mediastinal structures and heart toward the affected side.

**Prognosis.** Bilateral massive collapse is usually rapidly fatal, although prompt bronchoscopic aspiration and artificial respiration may be lifesaving. In the unilateral cases the prognosis is usually good.

**Prevention.** Prophylaxis is of the greatest importance. The incidence of postoperative atelectasis can be reduced by adequate ventilation during anesthesia. After operation the child's position in bed should be changed frequently, collections of secretions in the oropharynx should be aspirated, and, when consciousness returns, the child should be encouraged to breathe deeply. Tight thoracic or abdominal binders should be avoided.

**Treatment.** When there is bilateral atelectasis, bronchoscopic aspiration should be performed immediately.

When there is only unilateral atelectasis, the child should be placed on the unaffected side. Forced coughing or crying while the child is lying on the unaffected side may also be helpful. When these measures are not successful, bronchoscopic aspiration should be performed.

Relapses are not infrequent, and the child should be kept under constant observation.

## EMPHYSEMA

Pulmonary emphysema is a distention or rupture of the alveoli. It may be localized and involve part or all of one lung, or it may be generalized. From an etiologic standpoint it may be compensatory or obstructive.

### COMPENSATORY EMPHYSEMA

This may be either acute or chronic. It occurs in normally functioning pulmonary tissue when for any reason a sizable portion of the lung is partially or completely airless as in association with pneumonia, atelectasis, empyema and pneumothorax.

### OBSTRUCTIVE EMPHYSEMA

Obstructive emphysema results from partial obstruction of a bronchus or bronchiole when the difficulty of getting air out of the alveoli is greater than getting it in, so that there is a gradually increasing accumulation of air distal to the obstruction. This is the so-called bypass or check-valve type of obstruction. Such obstructions may be intrabronchial or extrabronchial (see p. 802).

### LOCALIZED OBSTRUCTIVE EMPHYSEMA

When the main stem bronchus is occluded in this manner, the entire lobe is emphysematous; only individual lobules are affected when the obstruction is that of a secondary bronchus. Localized obstructions which may be responsible for emphysema include foreign bodies and the inflammatory reaction to them, intrabronchial tuberculosis or tuberculosis of the tracheobronchial lymph nodes and intrabronchial and lymph node tumors. When most or all of a lobe is involved, the percussion note will be hyperresonant over the area and the breath sounds decreased in intensity. The distended lung may extend across the mediastinum into the opposite hemithorax. Fluoroscopically, it can be observed that during expiration the emphysematous area does not decrease in size, and the heart and mediastinum shift to the opposite side.

*Congenital obstructive lobar emphysema* may account for severe respiratory distress in early infancy. A part or usually all of a lobe may be involved; the left upper lobe seems to be the one most often affected. In some instances there is no demonstrable obstruction,

FIG. 227. Congenital lobar emphysema in an infant 4 weeks of age. Severe dyspnea and wheezing of 4 days' duration. The left upper lobe is emphysematous and protrudes across the midline anteriorly (note lateral projection). The mediastinal structures are displaced to the right. Relief of symptoms followed removal of the left upper lobe.

INSPIRATION

EXPIRATION

FIG. 228. Generalized obstructive emphysema: dorsal projections of thorax in inspiratory (left) and expiratory (right) phases of respiration. Notice the relative failure of the lungs to empty in the expiratory phase. The left lung is less obstructed than the right (empties to a greater degree in the expiratory phase). This difference between the lungs is not apparent from a study of the diaphragm, which moves very little during respiration; it is evident, however, in the upper portions of the left lung space. (From Nelson and Smith: *J. Pediat.*, Vol. 26.)

but it is assumed to be produced by a check-valve type of mechanism. Such obstructions have been attributed to defective cartilage in the bronchi, mucosal folds which create a valvelike obstruction, bronchial stenosis and external compression by aberrant vessels, tumors and the like. When the distention is marked, the emphysematous lung compresses the unaffected lung below or above it and the contralateral lung by extending across the mediastinum (Fig. 227). In most instances lobectomy is indicated.

Emphysema of all three lobes of the right lung has been produced by anomalous location of the left pulmonary artery, which partially constricts the right main bronchus.

#### GENERALIZED OBSTRUCTIVE EMPHYSEMA

This depends upon widespread involvement of the bronchioles. It occurs more commonly in infants than in older children and may be secondary to a number of different clinical conditions, including respiratory infections associated with cystic fibrosis of the pancreas, acute bronchiolitis or interstitial pneumonitis, atypical forms of acute laryngotracheobronchitis, aspiration of zinc stearate powder, chronic passive congestion secondary to a congenital cardiac lesion, and miliary tuberculosis. Asthma is a relatively frequent cause

in older children, but an uncommon one in infants.

The emphysematous portion of the lung is paler than usual, usually a light pink, and is distended and does not readily collapse. In chronic emphysema there is permanent loss of elasticity; many of the alveoli are ruptured and communicate with one another, producing distended saccules. As a result of the rupture of the alveoli, air may enter the interstitial tissue (*interstitial emphysema*) and result in pneumomediastinum and pneumothorax.

**Clinical Manifestations.** Generalized obstructive emphysema is characterized by an expiratory type of dyspnea. Owing to the relatively greater difficulty in expiration than in inspiration, air is trapped in the alveoli, the lungs become increasingly overdistended, and the chest remains expanded during expiration. Just the reverse happens in laryngeal obstruction, in which interference with exchange of air is relatively greater during inspiration and the lungs cannot be fully inflated. There is an increased respiratory rate and decreased respiratory excursions associated with the utilization of the accessory muscles of respiration. The overactivity of these muscles results in some inspiratory in-drawing at the suprasternal notch, the supra-

clavicular spaces, the lower margin of the thorax and the intercostal spaces, but this indrawing is not nearly so great as in laryngeal or tracheal obstruction. There is scarcely any reduction in size of the overdistended emphysematous chest during expiration, in contrast to the flattened chest during both inspiration and expiration when there is laryngeal obstruction. There is no hoarseness or stridor as there is in laryngeal obstruction; there is usually audible wheezing in asthma. Cyanosis is common in the severe cases. The percussion note is hyperresonant, and, on auscultation, the inspiratory phase is usually less prominent than the expiratory phase, which is prolonged and roughened. Fine or medium rales may or may not be present.

The roentgenographic and the fluoroscopic examinations of the chest are of the greatest help in establishing the diagnosis. Both leaves of the diaphragm are low and flattened, the ribs are farther apart than usual, and the lung fields are less dense. There is a marked restriction in the movement of the diaphragm (Fig. 228); this is demonstrated best by fluoroscopic examination. The normal "doming" of the diaphragm during expiration is decreased, and the excursion of the low, flattened diaphragm in the severe cases is barely discernible. Another evidence of retention of air in the lungs during expiration is a paradoxical increase in the horizontal diameters of the chest during this phase, suggesting that the emphysematous lungs are merely being forced into a different position by the diaphragmatic activity (the abdominal respiratory effort is relatively stronger than that of the intercostals) rather than emptied of any significant amount of trapped air.

#### **BULLOUS EMPHYSEMA**

Bullous emphysematous blebs or cysts (pneumatocele) result from overdistention and rupture of alveoli during birth or shortly thereafter (p. 781), or they may be sequels of pneumonia and possibly of other conditions. These emphysematous areas presumably result from the rupture of emphysematous alveoli so that a single or multiloculated cavity is formed. At times the cysts may assume large proportions (Fig. 222). They may contain some fluid, and an air-fluid level may be demonstrated on the roentgenogram. The differential diagnosis must be made from pulmonary abscess. In most instances the cysts disappear spontaneously within a few months, although they may persist for a year or so. There is almost never any indication

for treatment; aspiration or surgery should be avoided unless there is severe respiratory and cardiac embarrassment.

#### **SUBCUTANEOUS EMPHYSEMA**

Subcutaneous emphysema occurs whenever free air finds its way into the subcutaneous tissue. It may be a complication of a fracture of the orbit permitting air to escape from the nasal sinuses. In the neck and over the thorax, emphysema may follow tracheotomy, deep ulcerations in the pharyngeal region, esophageal wounds or any perforating lesion of the larynx or trachea. It is an occasional complication of thoracentesis. Air may also be formed in the subcutaneous tissues by gas-producing bacteria.

#### **PULMONARY EDEMA**

**Etiology.** Pulmonary edema results from escape of serous fluid from the pulmonary capillaries into the alveoli and bronchioles. It is usually a manifestation of circulatory or neurocirculatory collapse and is often a terminal condition. It may vary in severity, but even in its milder stages should be considered a serious omen. It is a common manifestation of myocardial failure in acute or chronic rheumatic carditis. It may be a manifestation of acute or chronic nephritis and of pneumonic and other infections which have a high degree of toxicity. Poisoning by a number of substances, such as the barbiturates, morphine, epinephrine and alcohol, may be responsible for the development of pulmonary edema, as may the asphyxiating gases and a number of the irritating gases used in warfare.

**Clinical Manifestations.** The onset is variable. The child often complains of a sense of oppression or pain in the chest. Cough is usually present and is often productive of a frothy sputum which may be blood-tinged. The cardiac action is weak and the pulse rapid and feeble. There is usually pallor and

cyanosis, and the child has an anxious expression. There may be some dullness to percussion over the lower portion of the chest, and there are numerous moist, bubbling rales, which are more marked in this area.

**Treatment.** Treatment depends upon the cause. The management of myocardial failure, nephritis and the various poisonings is discussed elsewhere. The fluid intake should be reduced, and the child should be placed in an oxygen tent with concentrations of oxygen maintained at 50 per cent or higher. Favorable experience with the use of an antifoaming agent in combination with pressure oxygen therapy has been reported in adults; the oxygen is bubbled through 50 per cent ethyl alcohol. The administration of morphine is helpful in quieting the child and often seems to have a favorable effect upon the edema. Atropine has been recommended, but is of doubtful benefit and should not be used if there is a coincidental infection responsible for a viscid bronchial secretion. If the child is in a state of shock, blood or plasma may be given intravenously, provided cardiac failure is not present and administration is by drip method to avoid strain on the heart.

### PULMONARY EMBOLISM AND INFARCTION

Pulmonary embolism as a recognized cause of disturbance in infants and children is rare. Emboli most often arise from thrombi in the femoral and pelvic veins and are usually post-operative complications. Fat emboli are most likely to be derived from fractured bones. Multiple pulmonary infarcts as evidence of small pulmonary emboli are occasionally found at autopsy. They are commonly associated with bacterial endocarditis and with longstanding nutritional deficiencies.

Embolism of the pulmonary artery or its larger branches is attended by a characteristic clinical picture. There is sudden pulmonary pain which is usually substernal, but may be pleural and radiate to the shoulder. There are dyspnea, tachycardia and signs of collapse. Though there are often no physical signs, if the infarct is sufficiently large (the base is at the periphery and the apex toward the mid-

line at the point of infarction), there may be impaired resonance and a pleural friction rub. Breath sounds may be distant or absent, and there may be moist rales. Expectoration, which may be profuse, often contains blood. The case fatality rate is high, but recovery may occur even when the area of infarction is relatively large. Secondary infection may result in abscess formation.

**Prevention.** The prevention of pulmonary infarction depends essentially upon two factors: (1) prevention of vascular stasis and (2) maintenance of a good nutritional status. The latter is especially important in bedridden children. Substances which decrease the coagulability of the blood such as heparin and Dicumarol have a limited usefulness in pediatric practice.

**Treatment.** The treatment of embolism of the larger branches of the pulmonary artery is a medical emergency. The child should be given morphine sufficiently often to induce quietness and allay fears, and should be placed in an oxygen tent for the relief of dyspnea and cyanosis.

### PULMONARY SUPPURATION

Pulmonary suppuration is due mainly to the combination of infection and blockade of bronchi. The principal lesions are bronchiectasis and pulmonary abscess; less frequent ones are pulmonary gangrene and chronic purulent bronchitis. Pulmonary abscess differs from gangrene of the lung in the extent and rapidity of the process. Both are necroses. The term "gangrene" is reserved for rapid involvement of large areas such as that of one or more lobes. Abscesses frequently develop in bronchiectatic lesions, and many primary abscesses leave as a residual some degree of bronchiectasis.

#### BRONCHIECTASIS

Bronchiectasis is a chronic, progressive, inflammatory disease of bronchi and their supporting tissues, resulting in denudation and dilatation of the bronchi, which serve as reservoirs for purulent material.

The condition is frequently overlooked for

years, being misdiagnosed as chronic bronchitis, asthma or recurrent pneumonitis. Often the symptoms date from an attack of pneumonia, measles or pertussis, any of which may be causative or the "trigger mechanism" for a pre-existing bronchiectasis. Congenital anomalies of bronchi may be responsible for bronchiectasis; Kartagener's syndrome, the triad of chronic sinusitis, bronchiectasis and situs inversus, is included in this group.

Chronic sinusitis, allergy, pulmonary abscess, foreign body, pancreatic fibrosis or bronchial occlusion from any cause such as neoplasm or tuberculous lymphadenopathy, may be the contributory factor.

**Pathology.** The fundamental change is dilatation of the bronchus, which is fusiform in the milder, and saccular in the more advanced form. There is thickening of the bronchial wall with loss of elasticity and decreased mobility. Mucosal changes are progressive with loss of cilia, a change from columnar to cuboidal and then to squamous epithelium and even complete denudation, leaving ulcerated, fibrosed and often bleeding surfaces. Stenosis may develop within the lumen; stagnation and accumulation of secretions favor the growth of anaerobic bacteria and the persistence of infection. There are variable degrees of peribronchial inflammation. One or more lobes may be affected, and the lower portions of a lobe are more likely to be involved than the upper portions.

**Clinical Manifestations.** Cough is the outstanding symptom. Usually it is productive of mucopurulent sputum, which young children ordinarily swallow, but may vomit during a paroxysm of coughing. Cough is often initiated by change of position such as lying down, rolling over, getting up or bending over which moves accumulated secretions to new locations. There is usually increased susceptibility to respiratory infections, which tend to be protracted. Repeated episodes of pneumonitis may be interpreted as influenza, pneumonia, pertussis, and the like. Bouts of fever are not uncommon and may be the only symptom. Remissions and exacerbations are the rule, with local progression and spread to new areas.

In severe cases retarded development, poor physique, dyspnea, clubbing of the digits and hypochromic anemia may occur.

Physical signs are variable and may be surprisingly minor or even absent. Moist rales are usually present, and in severe disease there may be a variety of manifestations pro-

duced by atelectasis, fibrosis, "drowned segments" and diffuse pneumonitis.

Roentgen examination may reveal heavy linear shadows radiating into the involved lobe, and atelectasis is relatively common, but the findings may be minimal and in any instance are not diagnostic. The diagnosis is established by bronchograms with opaque media (such as Dionosil or Lipiodol); it is essential to map the entire bronchial tree. More than 50 per cent of the unsatisfactory results of resection have been due to residual disease, which was not detected because of incomplete bronchographic delineation.

Bronchoscopy is essential to determine the presence of bronchial stenosis, tumor, compression or foreign body, and to obtain secretions for culture and tests of the susceptibility of the organisms to antibiotic agents. An adequate evaluation of the patient must also include examination for infected foci such as sinusitis, infected tonsils and oral sepsis, as well as for allergic disturbances.

**Treatment.** Removal of the diseased portions of lung is the only method of cure for saccular bronchiectasis and for the fusiform

FIG. 229. Bronchiectasis of the type ordinarily associated with long-standing upper respiratory tract infection. Bilateral fusiform bronchiectasis in the caudal portions of both lungs is usually secondary to severe chronic sinusitis. White male 18 years of age. History of chronic cough and expectoration from "bronchitis" since the age of 4 years. Pneumonia and bilateral empyema had occurred in the past year. Excision of left lower lobe and lingula of left upper lobe, followed in 5 months by resection of right lower lobe. All remaining lobes had been "mapped" and found normal. After recovery he attended college and was known to have been free of symptoms, except for slight decrease in respiratory capacity, for 9 years.

FIG. 230. Bronchiectasis in left lower lobe. A, The loss of volume of the diseased left lung has resulted in displacement of mediastinal structures. Much of the consolidation is hidden behind the heart in the ventral projection. B and C, Lipiodol bronchography reveals both types of bronchiectasis, fusiform and saccular. The patient was a white female 3 years of age who had pneumonia followed by empyema and rib resection 18 months before admission. Thereafter she had chronic cough and expectoration, a foul breath and occasional bouts of fever. After thorough study the entire left lung was removed in one stage. The patient was observed for 3 years, during which she had the ability to play normally and had no apparent respiratory deficiency.

type when there are persistent or recurring symptoms. Extremely mild degrees of fusiform bronchiectasis with little or no symptoms should be treated conservatively along the following lines: (1) elimination of such foci of infection as sinusitis, oral sepsis and infected tonsils; (2) avoidance of irritant dusts and of contact with respiratory infection; (3) desensitization to and avoidance of any allergens to which susceptibility has been demonstrated; (4) postural drainage, the child assuming the position which produces the greatest expectoration; (5) bronchoscopic aspiration once or twice weekly to assist in evacuation, to aid in aeration and so inhibit anaerobic infection, and the instillation of shrinking solutions in order to improve drainage and ventilation; (6) aerosol inhalations of antibiotic agents in conjunction with a proteolytic enzyme. The appropriate antibiotic agents should be determined by susceptibility tests on the bacteria obtained from cultures of bronchial secretions. Inhalations should be carried out two or three times each day for seven to ten days. Such courses can be repeated from time to time, but there is danger that the bacteria will develop resistance to the antibiotic agents. Systemically administered antibacterial agents have little direct effect on bronchial secretions, but are efficacious in the control of associated pneumonitis or parenchymal infection and in preparation for excision of the lung. (7)

Change of residence to a mild climate in which respiratory infections are infrequent may aid in decreasing the frequency of acute exacerbations.

**Postoperative Results.** Although lobectomy leaves the patient with less pulmonary area, his dyspnea is usually lessened, owing to decreased toxemia and to eradication of associated generalized bronchitis. Children who have had one or even two lobes removed seem to be capable of all the usual activities of childhood without evidence of respiratory difficulty. In adults external spirometry and bronchospirrometry bear out these clinical observations and often reveal better utilization of oxygen than preoperatively.

If all the diseased lung is removed and if the contributory factors such as infected sinuses and respiratory allergy are corrected, further bronchiectasis rarely develops.

#### PULMONARY ABSCESS

Multiple small pulmonary abscesses are seen in association with general sepsis, in pneumonia caused by the *Staphylococcus*, by Friedländer's bacillus and occasionally by other bacteria, and in the terminal phase of diffuse bronchiolitis, especially that associated with cystic fibrosis of the pancreas.

Single, nontuberculous abscesses may be due to aspiration of infected material or to infected emboli. The first is the more common and may be associated with tonsillec-

tomy, extraction of teeth and even dental hygiene procedures. Local anesthesia for tonsillectomy decreases but does not abolish the incidence, since, as demonstrated by bronchoscopy after operation, the regional anesthesia permits the otherwise unrecognized aspiration of the contents of the throat. A good many abscesses are insidious in onset and may have their origin from aspiration during sleep or from suppurative pneumonitis.

**Pathology.** An abscess is a localized area of suppurative necrosis and liquefaction which may be partially or completely evacuated into adjacent bronchi or occasionally into the pleural space. When the abscess erodes into a large bronchus, and drainage is adequate, healing may be fairly rapid and complete. Since, however, the abscess is usually near the periphery and the communicating bronchi are small, mucosal swelling and granulations in them contribute to inadequate drainage and thus to persistence and often spread of the abscess. Under these circumstances anaerobic bacteria thrive and a chronic infection, abscess or bronchiectasis, is established.

Perforation into the pleural space produces an empyema, usually of the "putrid" variety, which is extremely serious unless treated promptly. Infected emboli may be responsible for brain abscesses.

**Clinical Manifestations.** The onset is usually within one to four days after infection. There may be a persistent cough with little or no sputum at this time; the temperature is elevated as a rule ( $101^{\circ}$  to  $103^{\circ}$  F.), and there are such other evidences of sepsis as leukocytosis and malaise.

An area of consolidation in the lung may be detected clinically, but frequently it is not, owing to the locations of the abscess along the mediastinal border or at the extreme base. A roentgenogram of the chest at this time will reveal an area of induration which is often wedge-shaped and usually evenly consolidated (Fig. 231). Unless some other pulmonary lesion is responsible for the abscess, expectoration is not a prominent feature until rupture occurs into a bronchus, when there is a definite increase in the amount of purulent sputum, which often has an offensive, putrid odor. Rarely the quantity of pus discharged at the time of rupture of the abscess is sufficient to drown the child. Hemoptysis is often present during this phase, but may also be present at any time in the course of the disease. When drainage from the abscess is adequate, there is rapid subsidence of symptoms within two to four weeks, with rapid disappearance of the physical and roentgenographic evidences of infection. The cavity is usually demonstrable on the roentgenogram after the abscess has ruptured and until healing has occurred. At times the cavity may again become completely filled with fluid and appear as a solid mass, but it usually is partially empty, and a fluid level can be seen. Clubbing of the fingers may develop within a few weeks, especially when there is some dyspnea and cyanosis.

**Treatment.** Early recognition of a suppurative pneumonitis and adequate systemic antibiotic therapy are often responsible for prevention of a pulmonary abscess or eradication of an abscess during the early stages of de-

FIG. 231. Pulmonary abscess in a white boy 8 years of age. The abscess followed tonsillectomy under general anesthesia 18 months previously. Conservative treatment before admission. Progressive excavation without clinical improvement occurred for 4 additional weeks during which bronchoscopic aspiration was done. The abscess was then drained externally. Recovery was rapid and satisfactory. Subsequently there were no symptoms for  $7\frac{1}{2}$  years in spite of Lipiodol evidence of a small persisting bronchiectatic cavity. Then after 6 months of cough and hemoptysis the right lower lobe was removed. The subsequent course was uneventful.

velopment. Supportive therapy consists in (1) liquefaction of secretions by a proteolytic enzyme and appropriate antibiotic agents; (2) removal of secretions by postural drainage and bronchoscopic aspiration; and (3) aspiration of the abscess under biplane or multiplane fluoroscopic guidance with simultaneous instillation of concentrated solutions of antibiotics. This last method has been dramatically effective and, combined with systemic administration of antibiotics, is the preferred method of treatment. Surgical drainage should be instituted when improvement is not manifest after the first week of treatment. Lobectomy is required for chronic lung abscesses and for residual bronchiectasis.

### PULMONARY GANGRENE

Gangrene of the lung is a rare condition at any age and especially in infants and children. The factors responsible for the rapidly destructive process of pulmonary gangrene are not understood.

**Pathology.** The characteristic lesion of gangrene consists of an irregular brownish or greenish-black necrotic area containing a single or many ragged ulcerated cavities. The process is usually confined to a single lobe, most frequently a lower one. Involvement of the pleura with the production of putrid empyema is not uncommon.

**Clinical Manifestations.** The principal symptoms are the extremely foul odor of the breath and the expectoration of putrid sputum, which may contain blood or have a prune juice appearance. At times there may be extensive hemorrhage. There is a high remittent fever, rapid pulse and profound prostration. The physical and roentgenographic findings are suggestive of either pneumonia or pulmonary abscess, unless the pleura is involved, when the findings are those of a pleural effusion.

**Prognosis and Treatment.** Subacute and

chronic forms of gangrene are rare, and in most instances death occurs in one to three weeks. The only hope lies in early surgical removal of the diseased portion of the lung in conjunction with appropriate antibacterial therapy, selected on the basis of cultures and sensitivity tests.

### REHABILITATION

After any infection or operation of the pleura, lungs or mediastinum, intelligently directed pulmonary and thoracic exercises can reclaim much, if not all, of the function which has been temporarily lost. This phase of treatment was developed to a remarkable degree in the Military Chest Centers during World War II. In small children such exercises can be supplanted by blowing horns or balloons or colored water from one bottle to another, changing colors to maintain interest. Early physical activity is advantageous to most convalescent patients and definitely shortens the period of disability.

## DISEASES OF THE PLEURA

### PLEURISY

Inflammatory reactions of the pleura may be divided into three general groups: (1) the dry or plastic form; (2) the serous or serofibrinous form; and (3) empyema, or the purulent form. A plastic pleurisy may eventually produce a serous exudate, and a serofibrinous pleurisy may become purulent. Pleuritic involvement is less frequent than

formerly because of the decreased incidence of tuberculosis and because of the early treatment of bacterial pneumonic infections with specific agents.

### DRY OR PLASTIC PLEURISY

Acute inflammatory changes of the pleura are often associated with pneumonia, especially pneumococcal pneumonia. Occasionally they occur in association with infections of

the upper respiratory tract; in some of these instances the pleuritic involvement so overshadows the initial infection that it appears to be primary. Occasionally it is a manifestation of rheumatic fever or of tuberculosis in children. Probably in all instances there is a serofibrinous effusion initially, which is not marked and is relatively quickly absorbed.

In mild cases the involvement is limited to the visceral pleura over the affected lung, but in more extensive cases the parietal layer is also involved. The pleura is rough, dry and lusterless and, in advanced cases, is covered with fibrin which may be in shreds or may form a thick, yellowish-green layer. After the acute phase, adhesions usually remain between the pleural surfaces. In tuberculous pleurisy tubercles are present, and thickening of the pleura is likely to be extensive.

**Clinical Manifestations.** The symptoms may be indefinite; in pneumonia they may be obscured by the primary disease. There may be pain over the affected region, or it may be referred to the abdomen, the shoulder or neck. It is exaggerated by deep breathing or coughing and disappears when the breath is held. Pain from apical pleurisy tends to be referred to the shoulder; that of diaphragmatic pleurisy to the abdomen, supraclavicular area or the neck. There may be some local tenderness on pressure. There is often a sharp, frequently occurring and painful cough. The child often lies on the affected side, since pain from respiratory movements is thus decreased. The percussion note is usually not impaired. A to-and-fro leathery friction rub heard through both phases of respiration may at times be detected over the involved area. It may be obscured by the presence of pneumonia or difficult to detect when there are fine, crepitant rales.

**Differential Diagnosis.** The possibility of *epidemic pleurodynia* should be considered, though, in the absence of an epidemic, differentiation may be impossible. When the pain is referred to the abdomen, *acute abdominal conditions* such as appendicitis and mesenteric adenitis must be considered. The prodromal pain of *herpes zoster* may be responsible for pain over the chest area, but in this infection the pain is not related to respiratory movement. A diagnosis of dry pleurisy is not complete without the establishment of its etiology. When there is an acute pneumonic process, it may be assumed that the pleurisy is related to it. In other instances, or when the pleurisy persists after the patient

has recovered from the pneumonia, *tuberculosis* must be eliminated as an etiologic factor.

**Treatment.** Treatment is directed toward the primary disturbance. Considerable relief from pain may be secured by immobilizing the chest, strapping it with adhesive plaster. This procedure, however, should not be utilized in the presence of pneumonia. An ice bag over the affected area may afford some relief, as may salicylates. When the pain is severe, codeine may be given.

#### SEROFIBRINOUS PLEURISY

Serous effusions in the pleural cavity are often tuberculous in origin (p. 459) and should be regarded as such until proved otherwise. Such effusions, however, may be a manifestation of rheumatic fever, of neoplasms which involve the pleura or are contiguous with it, and of nonpurulent pleural involvement during the course of pneumonia.

The effusion may be loculated or fill the pleural cavity. It is nearly always unilateral. Depending upon the amount of fibrin and leukocytes, the fluid is clear to slightly turbid. The exudate is absorbed with varying degrees of rapidity, but thickening of the pleura persists to some degree; in long-standing cases the thickening may be sufficient to be responsible for permanent changes in the percussion note.

**Clinical Manifestations.** Except perhaps for a greater degree of fever, the initial symptoms are likely to be similar to those of plastic pleurisy. Within a few days—rarely longer—fluid appears in the pleural cavity. If it is present in considerable quantity, the pain and cough are decreased, but dyspnea becomes obvious, and even orthopnea, and cyanosis may develop. In other instances the onset is insidious, the child makes no complaint, and the pleural fluid is discovered only on physical examination.

In patients with considerable effusion the interspaces on the affected side appear to be full and may even bulge. There is diminished expansion and broadening of the costosternal angle. Palpation reveals diminished or absent tactile fremitus and a distinct sense of fullness and of resistance in the intercostal spaces. The heart is displaced to the side opposite the effusion; the displacement is likely to be greater in effusions of the left pleural cavity. The percussion note is flat over most or all of the involved side of the chest in large effusions, but in smaller effusions the percussion note may be tympanitic above a lower

FIG. 232. Pleural effusion with characteristic outlines of encapsulation. In addition to the obvious collection of fluid between lung and axillary portions of ribs, there is evidence of some fluid at the mediastinal aspect of the left lung.

FIG. 233. Fluid and air encapsulated in the pleural space. There is obvious compression of part of the lung with some mediastinal displacement. Note straight line of fluid level due to presence of air.

area of dullness. Grocco's triangle or sign is present on the opposite side of the chest in extensive effusions. This consists in a triangular area of dullness, at the vertebral-diaphragmatic angle, the hypotenuse extending from the diaphragm to the sternal border.

If the effusion is on the right side, the lower border of hepatic dullness is likely to be depressed. Auscultatory signs are less consistent than in adults, especially in infants and small children. Breath sounds may be feeble or absent, though in many instances there is not much change, and in some instances there is actually an increased pitch suggestive of bronchial breathing, and the presence of pneumonia may be suspected. Not uncommonly, rales may be transmitted through a layer of fluid sufficiently thick to produce dullness on percussion. Friction sounds are at times heard above the level of the effusion. When the fluid is free and the patient is in the sitting position, the greatest amount will be found at the base. The fluid is readily demonstrated roentgenographically, there being a uniform shadow in the region of the fluid with a curved upper line (Fig. 232), unless air is also present, when the upper line of the fluid will be straight (Fig. 233). When the effusion is extensive, the diaphragm will be depressed and the cardiac shadow displaced to the opposite side. Roentgenograms taken in the lateral and oblique positions are of value both in differentiating the shadow from one caused by pulmonary consolidation and as a means for establishing more accurately the position of a localized effusion.

**Differential Diagnosis.** The principal problem is the differentiation between *serous* and *purulent effusions*. This can be done only by thoracentesis and examination of the fluid. An effusion which is initially serous may become purulent, especially when associated with a pneumonic infection. At times there may be difficulty in distinguishing between a small free or loculated collection of fluid and a pneumonic consolidation. Lateral and oblique roentgenograms are often helpful in this respect, but an exact diagnosis is often impossible without a thoracentesis. *Hydrothorax* may be suspected if there is myocardial or renal disease, if there is a generalized edema, and especially if there is a bilateral pleural effusion. The diagnosis is confirmed by examination of the fluid, which in hydrothorax has a low specific gravity (below 1.015), and the few cells present are mesothelial rather than leukocytic. *Massive collapse* of the lung gives rise to dullness on percussion and to feeble respirations. However, the diaphragm on the affected side is high, and the heart is displaced toward and not away from the affected side. A *pericardial effusion*, if large in amount, may simulate pleural effusion of the left side, but a distinc-

tion can usually be made by fluoroscopic and roentgenographic examination. Nonpurulent fluid should always be examined for the presence of tubercle bacilli.

**Course and Prognosis.** Both the course and prognosis depend upon the underlying disease. When the effusion is associated with an acute pneumonic process, there is a strong possibility that it may become purulent, but in many instances the fluid is quickly absorbed when the pulmonary infection is controlled. In tuberculosis and rheumatic fever, effusions may persist longer, but even with these infections there may be a rapid disappearance of the fluid. In most instances there are residual adhesions and some pleural thickening, but as a rule there is little if any residual respiratory embarrassment.

**Treatment.** Rarely is treatment required for the serous effusion, the treatment being that of the underlying disease. Occasionally, symptoms of compression are of such an order that removal of fluid is indicated.

#### PURULENT PLEURISY

##### (EMPHYEMA)

Purulent pleurisy is an accumulation of purulent fluid in the pleural space which may be localized (encapsulated) or may involve the entire pleural cavity. The incidence has been greatly reduced by the effective treatment of bacterial pneumonias. Pneumococcal and streptococcal empyemas are now uncommon except in untreated or inadequately treated cases of pneumonia. The incidence is highest in infancy, the majority of infections being caused by the *Staphylococcus* and less frequently by various gram-negative bacilli.

**Pathology.** Both massive and loculated empyema produce notable thickening of the overlying parietal pleura and some thickening of the visceral pleura and, if not previously present, pneumonitis of the adjacent lung tissue. When the empyema is not drained surgically, there is a tendency to burrow into lung tissue with partial excavation of the pus through bronchi, producing bronchopleural fistulas. Rarely the chest wall is penetrated, and the pus appears under the skin as an *empyema necessitatis*. Even less frequently the pus may break through the diaphragm. There is a continued thickening of the serous surfaces so that chronic, thick-walled cavities may be produced in the pleura which are difficult to eradicate, even by adequate drainage. Massive empyemas which are

not properly treated in their early stage lead to fibrosis of the lung in a collapsed position, necessitating decortication or extensive thoracoplastic surgery. When recovery takes place under proper treatment, adhesions will result, but they usually cause no obvious respiratory embarrassment, although bronchspirometry will usually show lessened function on the affected side.

**Clinical Manifestations.** When empyema follows a pneumonic infection, there may or may not be a symptomless interval. In older children who have had sufficient antibacterial treatment to suppress their pneumonic lesion without eradicating the organism, there may be an interval of several weeks. The onset in such instances as in those with no preceding pneumonia is marked by irregular fever, increased rapidity of the pulse and respiration, dyspnea, cough and prostration.

In infants staphylococcal empyema is usually a continuation of a pneumonic infection, either an acute pneumonitis or a chronic one as with cystic fibrosis of the pancreas, less frequently of a staphylococcal infection elsewhere. Unless one is aware of the relative frequency with which infections may occur in infants with little or no febrile response and of the lesser frequency of symptoms related to the lesion itself, not only the location but also the presence of the infection may be missed until the infant is practically moribund. Any of the symptoms characteristic of pneumonia and empyema may be present in mild or severe form, or there may be only pallor, prostration and anorexia.

The physical signs of empyema usually do not differ from those characteristic of serous effusion. Breath and voice sounds, are not decreased to the same extent with pleural effusions in infants and small children as they are in adults. Effusions of sufficient extent to be responsible for flatness to percussion often permit the transmission of breath sounds with relatively little reduction in their intensity or apparent volume. Failure to recognize this fact may be responsible for serious delay in diagnosis and hence in treatment. When the pus is localized, it is usually at the base, but it may be near the apex, between two of the lobes of the lung or between the lung and the mediastinum. Pulsating empyema is rare in children.

**Diagnosis.** The differential diagnosis of pleural effusions is discussed on page 814. A roentgenogram will usually confirm the presence of fluid in the pleural space, but the

type of fluid can be demonstrated only by thoracentesis. The fluid should be examined for the presence of bacteria by direct smear and culture, and antibiotic susceptibility tests should be obtained immediately.

**Complications.** Local complications include purulent pericarditis, pulmonary abscess, bronchial fistula, pyopneumothorax and—after operation—osteomyelitis of the ribs. Blood stream infection may account for such foci as meningitis, arthritis and peritonitis; the last may also occur by rupture through the diaphragm. In long-continued cases clubbing of the fingers may develop.

**Course and Prognosis.** Mortality rates are directly related to the promptness of starting therapy and its adequacy. The recovery from empyema treated early is usually complete, the lung expanding fully and little if any deformity of the chest remaining. If operation is unduly delayed, there is danger that unyielding adhesions will persist, with failure of the lung to expand and resultant contraction of the chest wall.

**Treatment.** The accumulation of small pleural effusions which contain few or no bacteria is not an unusual manifestation of pneumococcal pneumonia. These collections of fluid often disappear without the production of empyema.

Treatment of the underlying cause is essential. Although it is feasible to obtain cure in adults by multiple aspirations and instillation of antibiotics and fibrolytic agents (such as streptokinase and streptodornase, trypsin or pancreatic dornase), the process is too uncomfortable, abhorrent and prolonged for children. Closed or controlled drainage of the pleura by intercostal tube inserted under local or general anesthesia is preferable. This can be instituted without delay unless the patient is too ill to withstand anesthesia, when preliminary preparation and support may be necessary. A polyethylene tube, inserted through a large needle, may suffice; such drainage allows control of the intrapleural pressure. The lung tends to re-expand rapidly as fluid is removed, and the infection is usually controlled by instillation of appropriate antibiotics and fibrolytic agents.

Antibiotics should also be administered systemically. Pulmonary exercises with the aid of blow bottles, balloons or horns will hasten obliteration of the empyema cavity.

The presence of a bronchopleural fistula may require mechanical suction; irrigation should be avoided. Such lesions usually do not significantly delay recovery.

## PUTRID EMPYEMA

This malodorous infection of the pleura is produced by anaerobic hemolytic streptococci in combination with various other organisms such as nonhemolytic streptococci, staphylococci and Vincent's fusospirochetal organisms. This type of infection is significant for the following reasons: (1) It is practically always secondary to pulmonary suppuration. (2) It is the only form of empyema which will produce phlegmonous infection along the tract of aspiration with any degree of regularity. (3) It causes severe toxemia, and there may be sudden peripheral vascular collapse. The fatality rate is high if much time elapses between the occurrence of the disease and surgical drainage. Often the underlying pulmonary suppuration can be drained at the same operation. Even though it has perforated into the pleura, the abscess may be inadequately drained, and more thorough drainage is indicated if the focus can be located.

## PNEUMOTHORAX

Pneumothorax in the newborn period may be related to factors incident to birth and be associated with interstitial emphysema and pneumomediastinum (p. 328). In staphylococcal pneumonia in infancy the incidence of pneumothorax is relatively high (p. 792). Aside from the accidental introduction of air into the pleural cavity during thoracentesis, pneumothorax is uncommon during childhood. Pneumothorax may occur in pneumonia, usually in connection with empyema; it may also be secondary to pulmonary abscess, gangrene, infarct, rupture of a cyst or an emphysematous bleb, foreign bodies in the lung and external thoracic trauma or surgical procedures. In association with mediastinal emphysema it is an occasional complication of tracheotomy.

Pneumothorax may be associated with a serous effusion (*hydropneumothorax*) or a purulent effusion (*pyopneumothorax*). In pneumothorax the lung collapses toward the

hilum, unless prevented by adhesions. Rarely is there a bilateral pneumothorax.

**Clinical Manifestations.** The onset is usually abrupt. When the pneumothorax is extensive, there is likely to be pain, dyspnea and cyanosis. In infancy both the symptoms and physical signs may be difficult to recognize. If the pneumothorax is only moderate in extent, there may be little or no displacement of intrathoracic organs and few or no symptoms.

The percussion note over the involved area is tympanic; on auscultation respiratory sounds are feeble or absent. The larynx, trachea and heart may be shifted toward the unaffected side. The breath sounds may have an amphoric quality if there is an open fistula from air-bearing tissues into the pleural cavity. When fluid is present, there is usually a sharply delimited area of tympany above a level of flatness to percussion. In evaluation of a case it is important to determine whether the pneumothorax is an open (*tension pneumothorax*) or a closed one. The presence of amphoric breathing or of gurgling sounds synchronous with respirations when fluid is present in the pleural cavity is suggestive of an open fistula. Confirmatory evidence is provided when the pneumothorax fills rapidly after aspiration of it. Another means for determining whether there is an open fistula is examination of the aspirated air for its oxygen content. If a fistula is present, the oxygen content of the air in pneumothorax remains constant. If there is no connection with the bronchial tree, the oxygen content is low, since it is rapidly absorbed. The diagnosis can usually be established by roentgenographic examination (Fig. 234).

**Differential Diagnosis.** Pneumothorax must be differentiated from localized or generalized emphysema, from an extensive emphysematous bleb, from large pulmonary cavities or other cystic formations, from diaphragmatic hernia and from gaseous distention of the stomach. In most instances a simple roentgenogram will be all that is necessary for the differentiation. In the case of diaphragmatic hernia, however, a small amount of barium may be necessary to demonstrate that a portion of the gastrointestinal tract is in the thoracic cavity.

**Prognosis and Treatment.** The prognosis depends upon the cause. When there is no fistula connecting the air-bearing tissue and the pneumothorax, the air is usually absorbed within a week or so, and no treatment is nec-

FIG. 234. Pneumothorax. Note the atelectasis of a large part of the right upper lobe with continued partial aeration of middle and lower lobes. Adhesions between the chest wall and lung are apparent at several points.

essary unless there are symptoms of excessive pressure, when the air should be aspirated.

Tension pneumothorax with a communicating fistula is usually best managed with a closed thoracotomy and drainage of the trapped air through a catheter whose external opening is kept in a dependent position under water. If the bronchopleural fistula is large, negative pressure in the drainage tube may be necessary. If the tension pneumothorax is not relieved by this means, surgical closure of the fistula should be considered. Treatment of a coexisting empyema is of course essential (p. 816).

## HYDROTHORAX

In hydrothorax, the fluid is noninflammatory in origin and has a lower specific gravity (less than 1.015) than that of a serofibrinous exudate. It contains less protein and fewer cells, which are mesothelial rather than leukocytic, and is usually associated with an accumulation of fluid in other parts of the body such as the peritoneal cavity and the subcutaneous tissues. Hydrothorax is most often associated with cardiac or renal disease, although on occasion it may be a manifestation of severe nutritional edema, and rarely it results from venous obstruction by neoplasms, enlarged lymph nodes or adhesions. Hydrothorax is usually bilateral in renal disease and in nutritional edema and may be in myocardial disease, although in this instance

it may be limited to the right side, or the accumulation of fluid may be greater on the right than on the left side. The physical signs are those described under Serofibrinous Pleurisy (p. 813), but there is more rapid shifting of the level of dullness with changes of position. The *treatment* is that of the primary disorder, although aspiration may be necessary when pressure symptoms are marked.

## HEMOTHORAX

Extensive bleeding into the pleural cavity may result from erosion of a blood vessel in association with such inflammatory processes as tuberculosis and empyema, but is not common. It is also an occasional manifestation of intrathoracic neoplasms, various blood dyscrasias, and may be the result of thoracic trauma. Rupture of an aneurysm is not likely during childhood. When a pleural hemorrhage occurs in association with a pneumothorax, it is termed *hemopneumothorax*. The *diagnosis* of a hemothorax can be made only by thoracentesis. In every instance an effort must be made to determine the cause, the *treatment* obviously depending upon it. Surgical intervention may be required to control active bleeding, and transfusion is necessary when loss of blood is excessive.

## CHYLOTHORAX

Chylothorax is a rare condition at any age, but especially in childhood, although it has been observed in infants even during the neonatal period. It depends upon the escape of chyle from the thoracic duct into the thoracic cavity. In the majority of instances thoracic trauma is responsible for rupture of the duct, but the escape of chyle apparently can occur without rupture of the duct as a result of pressure by enlarged lymph nodes or neoplasms. Thrombosis of the duct or the

subclavian vein and congenital anomalies of the duct system have also been reported as causes. Chylothorax is rarely bilateral, usually being on the left side.

The *symptoms* and physical signs are those related to the presence of fluid in the thoracic cavity. The *diagnosis* is established by thoracentesis and the demonstration of a chylous effusion, a milky fluid containing fat, protein and other constituents of chyle. A pseudo-chylous milky fluid has been reported in cases of serous effusion in which the fatty material was assumed to be due to the degenerative changes within the fluid and not to the presence of lymph. It has been suggested that this type of fluid can be distinguished from one containing chyle by shaking with alkalis or ether, when the fluid containing chyle tends to become clear. Spontaneous recovery has occurred in over half of the reported cases in infants under one year of age. Repeated aspiration may be required to relieve the symptoms of pressure. The aspirated chyle has been reinjected intravenously without untoward reactions, although there is some doubt whether it has any particular benefit. The diet should be low in fat content and high in protein. The lowered intake of fat is thought to be associated with a decreased production of chyle. The high protein intake is required because of loss of protein in the chyle. The total caloric intake must be above the average requirement, and several times the daily requirements of the various vitamins, especially the fat-soluble vitamins A and D, should be added.

# The Cardiovascular System

## THE HEART AND CIRCULATION IN HEALTH AND DISEASE

**Inspection and Palpation.** In early life the heart is situated somewhat higher in the chest in a more nearly horizontal position than in later years. The apex beat in the newborn infant may be palpated in the fourth left interspace in or just lateral to the left mid-clavicular line. After the age of two years the apical impulse is usually in the fifth intercostal space in or just medial to the mid-clavicular line. The flexibility of the mediastinum permits the heart to shift towards the side on which the patient lies. Although the relation of the apical thrust to the position of the mid-clavicular line is not an accurate index of cardiac size, it is helpful in making an estimate.

A hyperdynamic thrust, often extending over one or more interspaces, may accompany hypertrophy and dilatation of the ventricles. When the left ventricle is enlarged, the apex is likely to be one or two interspaces lower and farther to the left than normally. Enlargement of either ventricle, but especially of the right, tends to push the left side of the chest wall forward if the cardiac disease develops in early life, when the ribs are soft and pliable. Displacement of the apex beat to the right or left without cardiac enlargement may be caused by pulmonary conditions such as empyema, atelectasis or the collapse of one lung, and sometimes by scoliosis of the spine or defects of the diaphragm.

A clinical evaluation of ventricular hypertrophy can be made by palpation of the apical impulse. In the presence of right ventricular hypertrophy the sensation of a *tap* is transmitted to the hand, whereas in left ventricular hypertrophy the apical impulse is *heaving*. Right ventricular hypertrophy is usually associated with clockwise rotation of the heart, so that the right ventricle accounts for nearly all the anterior surface of the heart. This can be appreciated by palpation of a sternal and

a parasternal lift. Epigastric pulsations are commonly seen and felt in the presence of right ventricular hypertrophy, owing to the proximity of that chamber to the diaphragm. Biventricular hypertrophy can be suspected by a combination of the foregoing signs, namely, a sternal and parasternal lift associated with a left ventricular apical thrust.

*Thrills* may be detected during palpation; they should be timed in relation to the cardiac impulse or carotid pulse. If the child is able to cooperate with the examiner, thrills should be felt during full expiratory apnea. Apical thrills are felt more easily in the left lateral position, and basal thrills are more readily palpable with the patient sitting and leaning forward. Abnormal pulsations may also be detected, such as those produced by aneurysms or collateral vessels. Thrills are detected more readily with the palm of the hand than with the finger tips.

**Percussion.** Percussion of the cardiac borders in infants is difficult, owing to the thick layers of subcutaneous fat on the chest wall and the barrel shape of the thorax. Light percussion by direct tapping with the finger is generally preferable to the heavier double-finger method used in the examination of adults. Although the right border of the normal heart extends slightly to the right of the sternum, it can rarely be detected by percussion. Any dullness to the right of the sternum may suggest enlargement of the right ventricle or right atrium, or possibly the presence of pericardial effusion.

In the apical area any extension to the left beyond the usual limits may be due to enlargement of either ventricle or to pericardial effusion. The enlarged right ventricle tends to push the left border laterally, and the enlarged left ventricle extends downward as well as laterally. The value of percussion in the diagnosis of heart disease is frequently

overstressed. This method can be helpful in the evaluation of pericardial effusion, dextrocardia and movement of the mediastinum secondary to pulmonary or pleural space disease. Accurate assessments of cardiac size, shape and position can usually be made only by radiography.

**Auscultation.** In newborn and young infants the two heart sounds are about equal in intensity. Later in infancy the first sound becomes the louder of the two at the apex, and the second sound the more prominent at the base. Throughout childhood the second sound at the base is loudest in the second interspace to the left of the sternum and is often split into two distinct components.

The first heart sound is produced by closure of the atrioventricular valves; its intensity is governed mainly by the position of these valves at the beginning of ventricular systole. If the duration of atrial systole is comparatively long, the valve cusps have already partially returned toward the position of closure. Since the remaining distance through which they will move during ventricular systole will be short, the first heart sound will be of poor intensity. On the other hand, if atrial systole is short, the mitral and tricuspid valves are widely patent, and their closure produces a sound of greater intensity. Other factors which may modify the intensity of the heart sounds include the thickness of the chest wall, the amount of lung and mediastinal tissue covering the heart and perhaps the strength of ventricular contraction.

The second heart sound is produced by closure of the aortic and pulmonary valves, the aortic valve closing just before the pulmonary valve. This produces the normal splitting of the second heart sound, which is frequent in children and is often best heard at the end of inspiration. Recognition of variations of the normal splitting of the second heart sound is of considerable diagnostic importance. Wide splitting of this sound is often associated with conditions causing left-to-right shunting of blood such as may occur in atrial septal defect. In the presence of severe pulmonary stenosis the intensity of the systolic murmur frequently obscures the aortic element of the second heart sound. This produces a single second sound which arises from late closure of the pulmonary valve. In tetralogy of Fallot the pulmonary element of the second sound is not audible, resulting in a single second sound due to aortic valve closure.

Leatham has pointed out the clinical value of dividing systolic murmurs according to their recorded shape and relation to the heart sounds. According to their characteristics, systolic murmurs may be divided into two types: (a) ejection, (b) regurgitant.

**Ejection systolic murmurs** are produced by turbulence of blood flow through the aortic or pulmonary valves in the presence of stenosis, valvular damage without stenosis, poststenotic dilatation or increased flow through the valve. These murmurs are mid-systolic and usually basal. The interval between the first sound and the onset of the murmur depends on the time taken by the ventricle to raise its pressure sufficiently to open the aortic or pulmonary valve. The murmur rises in intensity in mid-systole and diminishes as the ventricle relaxes. The murmur ceases before the second sound.

**Regurgitant systolic murmurs** are pansystolic and caused by flow of blood from a chamber or vessel that is at a higher pressure throughout systole than the receiving vessel or chamber. In mitral or tricuspid incompetence the ventricular pressure rapidly exceeds that in the atrium. This backward flow results in a systolic murmur which begins soon after the first sound, continues throughout systole and tends to obscure the second sound.

Many attempts have been made to correlate the intensity of the second heart sound, especially the pulmonary element, with the degree of pulmonary hypertension. Although it is true that in many instances the second heart sound at the base is loud in the presence of moderate or severe pulmonary hypertension, this rule does not always apply. Thus the second heart sound may be loud in the presence of congenital heart disease and left-to-right shunt with normal or slightly elevated pressures in the pulmonary artery.

The sounds and murmurs produced by valves are not always heard at the positions on the chest wall to which these sounds might be expected to be transmitted. For example, the diastolic murmur of rheumatic aortic insufficiency is usually best heard over the pulmonary area and radiates down the left sternal border. Therefore care should be taken to auscultate the whole precordium and not to localize the examination to certain predetermined points on the left chest. Murmurs of congenital heart disease in children may be widely transmitted, so that it is necessary also to auscultate both sides of the neck and the back. On the other hand, the friction

of a pericardial rub may be localized fairly accurately over the area in the pericardium from which it emanates.

In older, cooperative children, sounds and murmurs may be more easily heard by varying the child's position, listening in various phases of respiration and by noting the effects of exercise. Thus mitral systolic and diastolic murmurs are more easily heard with the child in the left lateral position, especially after exercise, and basal murmurs are more obvious in the forward sitting position with the patient in full expiratory apnea.

**Innocent murmurs.** Little is known of the etiology of functional or accidental\* murmurs which are frequently heard throughout childhood. Leatham has recorded basal ejection vibrations in many normal subjects and suggests that some slight increase in their intensity is probably responsible for most innocent murmurs. In the newborn infant it is not unusual for soft systolic murmurs to be heard, usually to the left of the sternum in the third and fourth interspaces, but they generally disappear after a few days or weeks. In older children soft, blowing systolic murmurs may be heard in the area to the left of the sternum or at the base of the heart. They may become less audible or disappear completely when the patient changes from a supine to an upright position, after mild exercise or during various phases of respiration. Occasionally they remain constant under all conditions and persist until adolescence. Soft murmurs often develop during an acute illness or severe anemia and disappear during convalescence. The intensity of innocent systolic murmurs is usually increased during an intercurrent acute infection. Although the quality, location and variability of such murmurs usually indicate their innocuousness, frequent observation of the patient over a period of years may be required to make sure that no organic lesion is present.

A *venous hum* is produced by turbulence of blood in the jugular venous system. The hum has no pathologic significance and may be heard in the neck or anterior part of the upper chest. It produces a soft humming sound which may be heard in both systole and diastole. The murmurs can be exaggerated or made to disappear by varying the

\* The terms "functional" and "accidental" have been used synonymously to designate murmurs which appear to be unrelated to any cardiac disturbance or anatomic abnormality. Though common usage has been responsible for their continuation, the term "innocent" is recommended by the American Heart Association.

position of the head or by light compression over the jugular venous system in the neck. These simple maneuvers are sufficient to differentiate a venous hum from the murmurs produced by organic cardiovascular disease.

**Arterial Pulse.** The *cardiac rate* of newborn infants is rapid and subject to wide fluctuations. The average rate, ranging from 120 to 140 beats per minute, may increase to 170 or more during periods of crying and activity and drop to between 70 and 90 during sleep. As the child grows older the average pulse rate becomes slower. At the age of two it is about 110, at six years about 100, at ten years about 90, and the adult range of 70 to 80 is attained by the end of the adolescent period. After the age of about twelve years the pulse rate of boys is somewhat slower than that of girls. Table 95 lists rates compiled from several sources.

Throughout childhood the pulse rate is labile and increases rapidly in response to muscular activity or emotional stimuli. The average rate is generally higher in the afternoon than in the morning and more rapid after than before eating.

*Tachycardia* persisting for weeks or months has been observed in adolescent children, especially girls, without any discernible cause. Persistent tachycardia (over 200 in newborns, 150 in infants or 120 in older children) must be investigated to exclude pathologic arrhythmias. The apprehension induced by a visit to the doctor will often cause a fast rate at the time of examination. In order to determine the cardiac rate when it is not influenced by external stimuli, the parents may record the pulse rate several times throughout the day or night when the child

is quiet or asleep. In infants the pulsations of the carotid or temporal arteries may be easier to count than those of the radial artery.

*Slow pulse rates* are rare in children until the end of the adolescent period, when rates as low as 60 per minute may be encountered. If the pulse is persistently slower than this, some organic disturbance of the cardiac conductive mechanism must be suspected.

*The rhythm of the cardiac beat* in the newborn infant is often irregular and seems to be closely related to respiration. When the infant is asleep, there may be periods of apnea and a slow cardiac rate, but when respiratory movements are resumed, the pulse rate speeds up again. This arrhythmia is exaggerated in premature infants and in those who have suffered considerably from shock or possibly from intracranial hemorrhage. After the neonatal period and throughout the first few years of life the cardiac rhythm is generally regular, but by the age of about three years many children have a respiratory or *sinus arrhythmia* characterized by acceleration of the cardiac rate with inspiration and slowing with expiration. In some children this arrhythmia is marked, and careful examination may be necessary to determine that it is sinus in origin. Respiratory arrhythmia is most frequently associated with slow pulse rates and rarely occurs in children whose pulse rates have been accelerated by infection or cardiac disease. The presence of the arrhythmia is therefore generally considered to be evidence of normal cardiac action.

Diagnostic information may also be obtained by analysis of the *quality* and *amplitude* of the peripheral pulse. A water-hammer pulse in the forearm or a Corrigan pulsation in the carotid arteries signifies a large pulse pressure commonly found in patent ductus

arteriosus, aortic insufficiency or general vasodilatation. Capillary pulsation often accompanies such a finding. An anacrotic or plateau pulse of small volume signifies aortic stenosis, and pulsus bisferiens suggests combined aortic insufficiency and stenosis. Examination of the peripheral pulse should not be localized to the radial artery, but should include inspection and palpation of all major accessible arteries. Comparison of the amplitude of pulsation of the arteries on both sides of the body may help to localize a point of proximal compression. Routine examination of all infants and children should include palpation of the femoral vessels. Characteristically the femoral pulsation is diminished or delayed in nearly all cases of coarctation of the aorta.

**Arterial Blood Pressure.** It is often difficult to determine arterial blood pressure with accuracy in infants and young children. The patient must be quiet, and the arm cuff should be narrow enough so that it covers only about two thirds of the upper arm. With narrower cuffs erroneously high blood pressure readings are obtained, and the converse with wider cuffs. When the thigh is used as the site for measuring blood pressure, the cuff should likewise cover two thirds of the surface area of the thigh, especially when the pressure in this location is to be compared with that in the arm.

The blood pressure varies with the age of the child and is closely related to his height and weight. Significant increases occur during the adolescent period, and many temporary variations occur at this time before the more stable levels of adult life are attained. Exercise, excitement, coughing and straining may raise the systolic pressure of children as much as 40 to 50 mm. above their usual levels. Variability of blood pressure among children of approximately the same age and body build must be expected.

Table 96 was prepared by averaging data of the blood pressures of normal children from several studies. Standard deviations are in the range of 5 to 8.

In infancy and early childhood the blood pressure readings are approximately the same as those of the four-year-old child listed in the table. Any systolic pressure consistently above 120 mm. during childhood suggests some disease of the kidneys, heart, adrenals or blood vessels. In aortic insufficiency and patency of the ductus arteriosus there may be an elevation of the systolic pressure and a lowering of the diastolic pressure. In coarctation of the aorta there is frequently an in-

crease in the systolic and diastolic pressures of the arms and a decrease of pressures in the legs. Ordinarily the pressure in the legs is about 20 mm. of mercury higher than that in the arms. Lower than average pressures may be caused by shock, myocardial failure, pericardial effusion, aortic stenosis, Addison's disease or hypothyroidism.

**Venous Pulse.** Inspection of the cervical veins may yield considerable diagnostic information. The patient should be propped in bed at an angle of about 45 degrees with his neck muscles relaxed. Distention of the external jugular veins, owing to constriction of their passage through the deep cervical fascia, occurs in many normal children. Distention and pulsation of veins situated above the sternal angle are abnormal. In many instances an increased venous pressure is transmitted to the internal jugular vein in the form of venous pulsations. In these cases visible distention does not occur even though the venous pressure is raised. Of greater significance than distention are the presence and the quality of venous pulsations. Such pulsation does not occur in normal children reclining at an angle of 45 degrees. The height of venous pressure can be measured by observing the vertical height to which the distended and pulsating portion of the vein rises above the sternal angle. This clinical

observation is of great help, since the difficulties of measuring the resting venous pressure by venipuncture in small patients often preclude the determination of exact pressure.

Venous pulsations may be distinguished from those of arteries in the following ways (Wood): (1) Venous pulsations undulate, yield readily to pressure, vary with the position of the patient, and usually consist of multiple components, whereas those of the carotid artery are single, abrupt, only compressible with moderate pressure and do not vary with the patient's position. (2) Abdominal pressure, especially over the right hypochondrium, increases the height of the venous pulse, but has no effect on the arterial pulsation. (3) Mild compression of the external jugular vein in the supraclavicular fossa will abolish venous pulsations and distend the vein, but will not affect the carotid pulsation. (4) The height of venous pulsation will increase with expiration and decrease with inspiration. Arterial pulsations are not affected by respiration.

The normal jugular phlebogram or direct tracings from the superior vena cava show three positive components corresponding to each cardiac cycle. They are termed "a," "c" and "v" respectively (Fig. 235). The "a" wave is synchronous with atrial systole, the "c" wave with early ventricular systole and

FIG. 235. Diagram showing the relationship of various events of the normal cardiac cycle.

P.A. VIEW

L.A.O. VIEW  
A

R.A.O. VIEW

LATERAL VIEW  
B

the "v" wave with atrial diastole. Since the great veins are in direct communication with the right atrium, changes of pressure and volume of this chamber are transmitted to the veins. For example, (1) in congestive cardiac failure the increased right atrial pressure is transmitted to the cervical veins. The main pulsation at the upper part of distribution of these veins appears to be in late diastole. (2) Cardiac compression due to pericardial effusion or constriction increases the jugular pressure, but the amplitude of venous pulsation is small. (3) In relatively severe pulmonary stenosis the right ventricular diastolic pressure may be elevated. Emptying of the right atrium is dependent upon a systolic pressure in excess of the right ventricular diastolic pressure. A conspicuous presystolic "a" wave is present under these conditions. (4) A presystolic "a" wave is also frequently present in tricuspid stenosis or atresia, and the transmission of this wave to the inferior vena cava and hepatic veins produces presystolic hepatic pulsations. (5) In tricuspid insufficiency some of the right ventricular systolic pressure is transmitted to the right atrium, resulting in large conspicuous venous pulsations, which correspond to ventricular systole and produce a fusion of the "c" and "v" waves. (6) In complete heart block the occurrence of cervical venous pulsations will depend on the position of the tricuspid valve at the time of atrial systole. If the right atrium contracts when the tricuspid valve is closed, a large venous pulsation will occur. (7) In superior vena caval obstruction the jugular venous pressure is increased, but the veins do not pulsate.

Direct determinations may be made by inserting a needle in a peripheral vein. The venous pressure may be read on a water manometer, using the sternal angle as the reference point. By this method the average venous pressure of children over the age of three years is about 50 mm. of water (Lambert).

**Congestive Heart Failure.** In older children the signs and symptoms of congestive heart failure are similar to those in adults. In addition to breathlessness at rest, the systemic venous pressure is elevated as gauged by

clinical assessment of the jugular venous pressure, the liver is enlarged and tender and edema is present. Orthopnea and basal rales are commonly present, and edema usually occurs in dependent portions of the body. However, older children may occasionally prefer to lie in the flat position, which causes generalized anasarca.

During infancy the presence of congestive heart failure may be more difficult to determine. A clinical assessment of the jugular venous pressure in infants may be difficult, owing to the short structure of the neck and the difficulty of securing a relaxed state, although it should always be attempted. Edema in infants with cardiac failure is commonly generalized, involving the eyelids as well as the sacrum, legs and feet. Because right ventricular failure is more common than left ventricular failure in young patients, the classic signs of edema of the lungs are not commonly encountered. In infants breathlessness and hepatomegaly are constant signs of congestive heart failure, and a sudden increase in weight which decreases after diuretic therapy is common.

**Roentgenographic Examinations.** Roentgenographic examinations furnish the most accurate information of the cardiac size and shape. Many variations occur in normal persons, owing to differences in body build, abnormalities of the thoracic cage, the phase of respiration or cardiac cycle, subdiaphragmatic pressure or pulmonary disease which may displace the heart to one side or the other.

**Fluoroscopy.** Fluoroscopic examination provides important information, but since determination of size and configuration of the heart often requires detailed and prolonged observation, special precautions must be taken to adjust accommodation of the eyes and to protect the child and the physician from radiation. Not only the heart, but also the great vessels, lungs, thoracic cage and diaphragm must be observed.

In infants the thymic shadow may overlap the shadow cast by the base of the heart. In the anteroposterior view the left border of the cardiac shadow consists of three convex shadows from above downwards produced by the aortic knob, the pulmonary arc and the

FIG. 236. Idealized diagrams showing the normal position of the cardiac chambers and great blood vessels. Abbreviations are as follows: P.A., posteroanterior; L.A.O., left anterior oblique; R.A.O., right anterior oblique; S.V.C., superior vena cava; R.A., right atrium; R.V., right ventricle; P.A., pulmonary artery; R.P.A., right pulmonary artery; L.P.A., left pulmonary artery; L.A., left atrium; L.V., left ventricle; I.V.C., inferior vena cava. (Adapted and redrawn from Dotter and Steinberg: *Angiocardiographic Interpretation*. Radiology, Vol. 53.)

left ventricle, respectively (Fig. 236). In cases of moderate to gross left atrial enlargement the atrium may project between the opposing movements of the pulmonary artery and of the left ventricle. Angiocardiographic and cardiac catheterization studies have conclusively proved that the outflow tract of the right ventricle or the pulmonary conus does not contribute to the shadows formed by the left border of the heart (Fig. 236). In infants and children the aortic knob is not as easily visualized as in adults. Three structures also contribute to the right border of the cardiac silhouette. From above downward they are the superior vena cava, the ascending aorta and the right atrium. It is of fundamental importance also to assess the degree of pulmonary vascularity as represented by the intrapulmonary shadows. Angiocardiographic studies have shown that the hilar shadows are mainly vascular. Pulmonary overcirculation is usually associated with left-to-right shunts, and undercirculation with stenosis of the outflow tract of the right ventricle or pulmonary valve.

Fluoroscopic examination is not complete until the cardiac shadows have been studied in both oblique and lateral views (Fig. 236). The right anterior oblique view is optimal for the study of the left atrium and main pulmonary artery, whereas the left anterior oblique view is used for evaluation of the left and right ventricles, the aorta and the left atrium.

The esophagus is closely related to some of the cardiac chambers and great blood vessels, and its visualization with a barium emulsion helps to further delineate these structures, especially in the right anterior oblique view. The esophagus is indented in turn by the aorta, pulmonary artery and left atrium from above down. Permanent records of fluoroscopic findings may be made by accurate paper tracings (orthodiagraphy).

Interpretation of atrial or ventricular enlargement in infants and children by radiographic means is difficult. A hypertrophied ventricle may displace a normal chamber, giving a false impression of ventricular enlargement. Thus posterior displacement of a normal left ventricle by a hypertrophied right ventricle may cause the radiographic picture to resemble that of biventricular enlargement. The roentgenograms of patients with tetralogy of Fallot may not indicate the presence of right ventricular hypertrophy; conversely, the cardiac silhouette of patients with tricuspid atresia and an underdeveloped right ventricle may give the false impression of right ven-

tricular hypertrophy. It is therefore apparent that the radiographic findings should be complemented by an electrocardiogram, which is a more sensitive and accurate index of ventricular enlargement.

**Teleroentgenograms.** Taken with the roentgen tube approximately 6 feet from the patient, teleroentgenograms represent fairly accurately the size of the heart and chest. For a complete assessment of cardiac configuration, posteroanterior, oblique and lateral views are essential. The positions of the various cardiac chambers and great vessels are shown in Figure 236.

The most frequently used measurement of cardiac size is the maximum width of the cardiac shadow in posteroanterior teleroentgenograms. When the cardiac width is more than half of the maximal chest width, the heart is usually enlarged. In infancy the cardiothoracic ratio is a less accurate index of cardiac enlargement than it is in subsequent years, because the horizontal position of the heart may increase the ratio to more than half in the absence of true enlargement. In children with vertical hearts the cardiothoracic ratio will tend to give an erroneously low impression of the true heart size.

The width of the heart also bears a fairly definite relationship to other body measurements. The transverse diameter is approximately 7 or 8 per cent of the body height and is more closely related to this factor than to age or weight.

Cardiac area may prove helpful in borderline cases. To make this measurement, a curved line must be constructed at the base to connect the two angles produced by the junction of the great vessels and the heart. The inferior cardiac border, which lies beneath the shadow of the diaphragm, must be completed in an arbitrary fashion. The enclosed area may be measured by means of a planimeter. Tables comparing cardiac area and body size have been compiled (Hodges, Adams and Gordon).

**The Electrocardiogram.** The electrocardiogram in pediatric practice is not only of diagnostic aid in congenital and rheumatic heart diseases, but also is frequently helpful in the detection and management of disturbances of electrolyte metabolism, endocrine and metabolic diseases and acute infections. Electrocardiographic examination is not complete unless the standard leads are supplemented by the unipolar limb leads and multiple chest leads. It is beyond the scope of this text to discuss the physiologic concepts

FIG. 237. Electrocardiogram of a normal child. The position of the heart is vertical. Note the relatively tall R waves and inversion of the T waves in  $V_4R$  and  $V_1$ .

of unipolar electrocardiography. A study of standard leads is valuable in the diagnosis of arrhythmias and for the measurements of the duration of various parts of the cardiac cycle. Axis deviation usually denotes the electrical position of the heart. Thus right axis deviation is usually associated with a vertical heart with clockwise rotation\* and left axis deviation with a horizontal heart. Although the anatomic and electrical positions of the heart may coincide, this is not always the case.

A wide electrocardiographic exploration of the chest is advised in children and especially in infants. In addition to the conventional leads of  $V_1$  through  $V_6$ , leads over the right chest ( $V_4R$  or  $V_3R$ ) are essential for adequate assessment of right ventricular activity.

**The normal electrocardiogram.**† In the majority of children the electrical position of the heart is vertical with varying degrees of clockwise rotation (Fig. 237). In a minority of cases the heart may assume a horizontal position. The unipolar chest leads have a different pattern from that observed in the normal adult. In infants the right ventricular surface leads show an  $R_s$  pattern which usually persists for the first two years of life and may be found up to the age of four years (Fig. 238). The T waves are inverted in leads  $V_4R$ ,  $V_3R$ ,  $V_1$ ,  $V_2$  and  $V_3$  in almost all infants and may remain inverted in  $V_4R$ ,

$V_3R$  and  $V_1$  up to the middle of the second decade of life. However, in the first twenty-four to forty-eight hours of life the T wave is usually upright in  $V_4R$ ,  $V_3R$  and  $V_1$ , and may be inverted in  $TV_5$  and  $V_6$ . Because of these normal patterns of the QRS-T in infants and children, the changes produced by right ventricular hypertrophy are different from those in adults. The diagnosis of ventricular hypertrophy is sometimes based on the increased voltage of the R and S waves in the unipolar chest leads. However, since the height of these waves is mainly governed by the proximity of the exploring electrode to the surface of the heart and since the chest wall of infants and children is relatively thin, the diagnosis of ventricular hypertrophy should not be based on voltage changes alone. The normal electrocardiographic pattern of infants and children has been described by Ziegler and others.

**Electrocardiographic abnormalities.** See Abnormalities of Cardiac Rhythm (p. 883).

**The P wave.** Tall, narrow and spiked P waves are seen in congenital pulmonary stenosis (Fig. 239) and tricuspid atresia and sometimes in cor pulmonale. These abnormal waves are probably due to right atrial hypertrophy, are usually taller than 2.5 mm. and are most obvious in standard lead II,  $V_4R$ ,  $V_3R$  and  $V_1$ . Similar waves are sometimes seen in thyrotoxicosis. Flat and widened P waves, commonly bifid, are seen in chronic mitral stenosis and are probably due to left atrial hypertrophy. Flat P waves may be found in hyperkalemia. Inversion of the P wave occurs in all leads in nodal rhythm, in

FIG. 238. Normal infant's electrocardiogram. Note the tall R and small s waves in  $V_4R$  and  $V_1$  and the inverted T wave in these leads. The heart is vertical with clockwise rotation.

\* In clockwise rotations the right ventricle moves to occupy more of the anterior surface of the heart.

† In this text capitalized letters refer to waves of high voltage (tall or deep waves), and small letters are used to designate waves of low voltage.

FIG. 239. Electrocardiogram showing right ventricular hypertrophy in a 7-year-old boy with pulmonary stenosis. Note the tall, spiked P wave in lead II, qR in  $V_4R$  rsR' in  $V_1$  and inversion of the T wave in leads II, III, aVR, aVF and all the chest leads. The heart is vertical with clockwise rotation.

standard lead I in dextrocardia and occasionally in standard leads II and III without obvious cause.

**Prolongation of the P-R interval.** This abnormality is a form of heart block. Permanent prolongation of the P-R interval may be congenital or due to scarring from rheumatic carditis. Any active carditis, including acute rheumatic fever, may produce transient prolongation of the P-R interval. Other causes of temporary prolongation of the P-R interval include digitalis therapy and carotid sinus pressure. No treatment is required specifically for this abnormality.

**Right ventricular hypertrophy.** Right ventricular surface leads of infants and children differ from those of adults, and tracings of the right chest ( $V_4R$  or  $V_3R$ ) are essential in young children. Review of electrocardiographic tracings in infants with known right ventricular hypertrophy has shown that the following changes may occur singly or in combination (Fig. 240): (1) a qR pattern in the right ventricular surface leads; (2) a positive T wave in leads  $V_4R$  through  $V_3$  after the first twenty-four to forty-eight hours of life; (3) a monophasic R wave in  $V_4R$ ,  $V_3R$  or  $V_1$ ; (4) prolongation of the intrinsicoid

deflection in right ventricular surface leads to greater than 0.03 second; (5) the R wave in the right chest leads is usually taller than 7 mm., but this sign alone is not sufficient for the diagnosis; (6) aVR usually shows a QR pattern. It is uncertain whether this is due to right ventricular hypertrophy or to the clockwise rotation with which it is commonly associated. (7) In the presence of incomplete right bundle branch block, right ventricular hypertrophy is indicated by a tall secondary R wave.

Older children and adolescents who have right ventricular hypertrophy show the same changes, but in addition may have the following abnormalities of the R and S waves of the unipolar leads: (1) the sum of  $RV_1$  or  $RV_3R$  and  $SV_5$  or  $SV_6$  totals 11 mm. or more. (2) The depth of the S wave in  $V_1$ ,  $V_3R$  or  $V_4R$  is less than 2 mm. It cannot be overstressed that the evaluation of ventricular hypertrophy should not be based on voltage changes alone.

Cabrera and Sodi-Pallares have correlated abnormal hemodynamics with electrocardiographic patterns. They have shown that obstruction to right ventricular and pulmonary flow (e.g., with pulmonary stenosis and primary pulmonary hypertension) is associated with a *systolic overload pattern*. This is characterized by an increasingly tall and late R wave in the right precordial leads. In these leads the T wave is initially upright and later becomes inverted (Figs. 239, 240). In contradistinction *diastolic overload* of the right ventricle (e.g., with atrial septal defect) is characterized by the pattern of incomplete

FIG. 240. Electrocardiogram showing right ventricular hypertrophy in an infant with tetralogy of Fallot. Note the spiked P waves in lead II, monophasic R wave in  $V_4R$ , delay in the intrinsicoid deflection in  $V_4R$  and  $V_1$  and the positive T waves in  $V_4R$  and  $V_1$ .

FIG. 241. Electrocardiogram showing left ventricular hypertrophy in a 12-year-old boy with chronic rheumatic heart disease. Note the tall R in  $V_6$ , deep S in  $V_1$ , deep, wide Q and inverted T in aVL.

or occasionally complete right bundle branch block (Fig. 242). Although this concept appears to be true in extreme examples, there are many instances in which the dynamics of systolic overload may be associated with incomplete right bundle branch block.

**Left ventricular hypertrophy.** The following features, alone or in combination, suggest dominance of the left ventricle (Fig. 241): (1) depression of the S-T segment and inversion of the T waves in left ventricular surface leads (i.e.,  $V_5$ ,  $V_6$  or  $V_7$ ; aVF if the heart is vertical and aVL if the heart is horizontal); (2) delayed onset of the intrinsicoid deflection in  $V_5$  or  $V_6$  (greater than 0.04 second); (3) increased voltage of the QRS complex. In older children or adolescents the sum of the left ventricular potentials (i.e.,  $RV_6$  and  $SV_1$ ) is greater than 35 mm. Also  $RV_5$  or  $RV_6$  exceeds 26 mm. If the heart is vertical,  $RaVF$  exceeds 20 mm., and in a horizontal heart  $RaVL$  exceeds 11 mm. It is again stressed that the evaluation of ventricular dominance should not be based on voltage changes alone.

Cabrera and Sodi-Pallares have applied their concept of overload of the ventricles to the left heart. They suggest that *systolic overload of the left ventricle* is characterized by depression of the S-T segment and inverted T waves in the left precordial leads. *Diastolic overload of the left ventricle* is suggested by

tall R waves with a late activation time and tall upright and symmetrically peaked T waves in the left precordial leads. The foregoing electrocardiographic diagnoses, especially diastolic overload of the left ventricle, are frequently difficult to establish (Nadas).

**Bundle branch block.** Complete right or left bundle branch block is not frequently encountered in pediatric practice, and the electrocardiographic pattern does not differ from that in adults. However, *incomplete right bundle branch block* with or without right ventricular hypertrophy is not uncommon. Incomplete right bundle branch block is suggested by an early R wave and a late R' in the right precordial leads and a relatively broad  $SV_6$  (Fig. 242). If there is associated right ventricular hypertrophy, the secondary R wave in the right precordial leads is tall and usually exceeds 10 mm. It is often difficult to differentiate incomplete right bundle branch block from right ventricular hypertrophy.

**Duration of electrical systole (Q-T interval).** The duration of the Q-T interval (electrical systole) varies with the cardiac rate, and many formulas have been devised in an attempt to adjust this differential. Taran and Szilagyi's modification of Bazett's formula states that the corrected Q-T interval (Q-TC) equals the measured Q-T interval divided by the square root of the cycle length (R-R

FIG. 242. Electrocardiogram showing incomplete right bundle branch block in a patient with septal defect, in which there was a direct communication between the left ventricle and right atrium. Note the RSR' in  $V_4R$ , RSR's in  $V_1$  and stumpy S wave in  $V_6$ .

FIG. 243. Electrocardiogram in hypocalcemia and hypokalemia (serum calcium, 1.8 mEq./L.; serum potassium, 2.2 mEq./L. at time of tracing). Note prolongation of electrical systole due to long S-TU segment. This graph also shows left ventricular hypertrophy.

FIG. 244. Electrocardiogram in hypokalemia (serum potassium, 2.7 mEq./L.; serum calcium, 4.8 mEq./L. at time of tracing). Note the prolongation of electrical systole due to a widened TU wave, especially in leads II, III and aVF; also depression of the S-T segment in  $V_{4R}$ ,  $V_1$  and  $V_3$ .

interval). The normal Q-TC is variously given as 0.38 plus or minus 0.04. It is often lengthened in children with acute rheumatic carditis, myocarditis secondary to infections, hypokalemia and hypocalcemia (Figs. 243, 244). In hypokalemia and hypocalcemia prolonged electrical systole is due to a lengthened Q-U interval. A shortened Q-TC may be found after administration of digitalis and with pericarditis and hyperkalemia.

**S-T segment and T wave abnormalities.** In generalized pericarditis superficial epicardial involvement may cause elevation of

the S-T segment, which is later followed by abnormal T wave inversion as healing progresses. Administration of digitalis is associated with sagging of the S-T segment and abnormal inversion of the T wave. Depression of the S-T segment may also occur in conditions producing myocardial hypoxia, e.g., anemia and carbon monoxide poisoning.

A group of abnormalities of special interest which produce S-T segment depression and sharp inversion of the T waves and which usually cannot be differentiated by the electrocardiogram alone includes endocardial sclerosis, aberrant origin of the left coronary artery from the pulmonary artery, glycogen storage disease of the heart, myocardial tumors and gargoylism. Aberrant origin of the left coronary artery from the pulmonary artery may lead to changes indistinguishable from those seen in acute myocardial infarction in adults. Similar changes may occur in progeria with degenerative coronary artery lesions and calcinosis of the coronary arteries.

In any form of carditis, especially diphtheria, simple inversion of the T wave may occur. Hypothyroidism may produce flat or inverted T waves in association with a generalized low voltage graph. In hyperkalemia the T waves are commonly of high voltage and are tent-shaped (Fig. 245).

**Hematologic Data.** The normal variations of the blood picture in infancy should be borne in mind in evaluation of cardiovascular disease. These include the normal poly-

FIG. 245. Electrocardiogram in hyperkalemia. (Serum potassium, 6.5 mEq./L.; serum calcium, 5.1 mEq./L.) Note the tall, tent-shaped T waves, especially in leads I, II and  $V_6$ .

cythemia of the neonatal period and the relative anemia and leukocytosis of infancy. Persistent polycythemia after the first month of life is frequently associated with right-to-left shunts and cyanosis. Anemia and polymorphonuclear leukocytosis are often encountered in active rheumatic fever and in subacute bacterial endocarditis.

Patients with intense cyanosis may exhibit manifestations of an abnormal clotting mechanism. Laboratory studies may indicate any

combination of the following: prolonged bleeding and clotting times, decreased or abnormal platelets, decreased plasma fibrinogen or prolonged prothrombin time. These abnormalities frequently revert to normal after repeated venesection and have clinical importance when surgical therapy is being considered.

**Cardiac Catheterization.** The technique consists in passing a radiopaque catheter under sterile conditions into a peripheral vein

FIG. 246. Roentgenograms showing the positions of the cardiac catheter from which pressures and blood samples may be obtained. A, Superior vena cava. Catheter inserted from antecubital vein. B, Inferior vena cava. Catheter inserted from saphenous vein. C, Low right atrium. D, Right atrium in region of tricuspid valve. E, Low right ventricle. F, High right ventricle in region of outflow tract. G, Main pulmonary artery. H, Left pulmonary artery. I, Right pulmonary artery.

**FIG. 247.** Roentgenograms showing positions of the cardiac catheter. *A*, Coronary sinus: compare with Figure 246, *F*. *B*, Pulmonary wedge or "capillary" via left pulmonary artery. *C*, Catheter has passed from the right to left atrium across an atrial septal defect. *D*, Catheter has passed across an atrial septal defect and entered a right pulmonary vein. This picture is frequently confused with an anomalous pulmonary vein across an atrial septal defect. *E*, Catheter tip in a left pulmonary vein after passing from the right to left atrium across an atrial septal defect. *F*, Catheter has passed from the inferior vena cava into the right atrium, across an atrial septal defect into the left atrium, and then through the mitral valve into the left ventricle. *G*, Catheter has passed from the superior vena cava to the right atrium, right ventricle and pulmonary artery, through a patent ductus arteriosus and down the descending aorta. *H*, Retrograde catheterization of the aorta from the femoral artery. The catheter tip has passed across a patent ductus arteriosus into the pulmonary artery. *I*, After coiling in the right atrium the catheter has passed into the right ventricle, then through a ventricular septal defect into the aorta.

and guiding it with the aid of fluoroscopy into the great veins, the right heart chambers and pulmonary artery (Fig. 246). In some congenital cardiovascular abnormalities the catheter may pass through intracardiac defects or into abnormally placed vessels (Fig. 247). Samples of arterial blood may be obtained simultaneously from an indwelling needle in the brachial or femoral arteries. Oxygen consumption and carbon dioxide production may be calculated from samples of

expired air collected in Douglas bags. These studies are of value in determining the presence of intracardiac shunts and pressures, as well as measurements of cardiac outputs and indices. Calculations may also be made of the pulmonary and peripheral arteriolar resistances, the work of the heart, the volume of various shunts and the areas of intracardiac defects and valves.

Cardiac catheterization in infants and children presents many problems not encountered

in adults. In many instances it is necessary to sedate or even anesthetize the patient. Volatile gas mixtures such as ether should not be used, because manometric blood analyses done in the presence of these substances are inaccurate. The calculations of cardiac output, shunts, resistances and valve areas should be interpreted cautiously if the study is made during anesthesia because their validity depends upon the patient being in a "steady state," which is difficult to obtain during deep narcosis.

The majority of congenital cardiac lesions can be diagnosed after a careful clinical history and examination, and cardiac catheterization should not be used indiscriminately in young patients because of the hazards of injury and even of death. Suitable laboratory facilities which must be available before the study is undertaken include a fluoroscope, electrocardiograph and apparatus for recording blood pressures and for analysis of the oxygen and carbon dioxide content of blood.

Abnormal findings which may be encountered in patients with congenital heart disease are shown in Tables 98 and 99.

**Dye Dilution Curves.** Localization of intracardiac and extracardiac shunts may be facilitated by injection of an indicator dye at multiple sites in the heart and great vessels during cardiac catheterization. Dye dilution curves may be recorded by means of ear piece and cuvette oximeters. The shape of the dye dilution curve depends on the site of injection of the dye and the presence or absence of intracardiac and extracardiac shunts (Fig. 248).

The dye most frequently used is T-1824 (Evans blue). A disadvantage of this material is that multiple injections result in a blue discoloration of the skin. Other dyes are now available which overcome this problem. This technique can also be used for measurement of cardiac output and for the assessment of competence of the cardiac valves.

**Arterial Oxygen Saturation.** The arterial

Table 97. Normals and Formulas for Determination of Hemodynamics in Cardiac Catheterization

1. Cardiac index  $3.1 \pm 0.4$  liter/minute/square meter
  2. Arteriovenous oxygen difference  $4.5 \pm 0.7$  ml./100 ml.
  3. Oxygen consumption 160–180 ml./square meter/minute
  4. Arterial oxygen saturation 94–100%
  5. Difference in oxygen content between venae cavae and right atrium  $< 1.9$  vol. %
  6. Difference in oxygen content between right atrium and right ventricle  $< 0.9$  vol. %
  7. Difference in oxygen content between right ventricle and pulmonary artery  $< 0.5$  vol. %
  8. Normal mean left atrial pressure 4 to 8 mm. Hg
  9. Pulmonary arteriolar resistance 50–150 dyne sec. cm.<sup>-5</sup>
  10. Cardiac output ml./min. = 
$$\frac{\text{O}_2 \text{ intake (ml./min.)}}{\left\{ \begin{array}{l} \text{O}_2 \text{ content arterial blood (vols. \%)} \\ \text{minus O}_2 \text{ content of mixed venous blood} \end{array} \right\}} \times 100$$
  11. Cardiac index = cardiac output (L./min.) per square meter of body surface area
  12. Pulmonary artery flow = 
$$\frac{\text{O}_2 \text{ intake (ml./min.)}}{\left\{ \begin{array}{l} \text{O}_2 \text{ content of pulmonary venous blood (vols. \%)} \\ \text{minus O}_2 \text{ content of pulmonary arterial blood (vols. \%)} \end{array} \right\}} \times 100$$
  
If a pulmonary venous sample is not obtained, it is assumed to be saturated 95% of capacity
  13. Systemic flow = 
$$\frac{\text{O}_2 \text{ intake (ml./min.)}}{\left\{ \begin{array}{l} \text{systemic arterial O}_2 \text{ content (vols. \%)} \\ \text{minus mixed venous O}_2 \text{ content (vols. \%)} \end{array} \right\}} \times 100$$
  14. Effective pulmonary artery flow = 
$$\frac{\text{O}_2 \text{ intake (ml./min.)}}{\left\{ \begin{array}{l} \text{pulmonary venous O}_2 \text{ content (vols. \%)} \\ \text{minus mixed venous O}_2 \text{ content (vols. \%)} \end{array} \right\}} \times 100$$
  15. Total left-to-right shunt = pulmonary artery flow minus effective pulmonary artery flow
  16. Total right-to-left shunt = systemic flow minus effective pulmonary artery flow
  17. Pulmonary arteriolar resistance  $R = \frac{PA - PC}{PF} \times 1332$
- Where  $R$  = pulmonary arteriolar resistance in dyne seconds cm.<sup>-5</sup>  
 $PA$  = mean pulmonary artery pressure in mm. Hg  
 $PC$  = mean pulmonary "capillary" pressure in mm. Hg  
 $PF$  = pulmonary flow in ml./sec.

Table 98. Analysis of Oxygen Content in Blood (Cardiac Catheterization)

	Venae Cavae	Right Atrium	Right Ventricle	Pulmonary Artery	Arterial Oxygen Saturation	Remarks
Patent ductus arteriosus	←————Comparable————→		————→	Higher than R. V., R. A. and V. C.	Normal	(a) Rarely, with right-to-left shunt, arterial unsaturation present (b) If associated pulmonary valve insufficiency, high R. V. samples comparable to P. A.
Atrial septal defect	Lower than R. A., R. V. and P. A.	←————Comparable————→	————→	————→	Normal	
Ventricular septal defect	←————Comparable————→	————→	←————Higher than R. A. and V. C.————→		Normal	Rarely, direct shunt into P. A. without mixing in R. V. when P. A. higher than R. V., R. A. and V. C.
Anomalous pulmonary veins	(a) If empty into S. V. C., I. V. C. lower than S. V. C., R. A., R. V. and P. A. (b) If empty into I. V. C., S. V. C. lower than I. V. C., R. A., R. V. and P. A.	If empty into R. A., V. C. lower than R. A., R. V. and P. A.	←————Comparable————→		Normal	
Isolated pulmonary stenosis	←————Comparable————→	————→	————→		Normal	If right-to-left shunt, e.g., through foramen ovale, arterial unsaturation
Aorticopulmonary septal defect	←————Comparable————→	————→	————→	Higher than R. V., R. A. and V. C.	Normal	
Tetralogy of Fallot	←————Comparable————→	————→	————→		Usually gross unsaturation	In many instances R. V. and P. A. samples higher than R. A., and V. C. Venous blood grossly unsaturated
Tricuspid atresia	←————Comparable————→	————→	————→		Usually gross unsaturation	
Transposition of great vessels	Depends on presence of associated defects such as atrial defect, ventricular septal defect and patent ductus arteriosus				Gross unsaturation	Contents vary in same chamber because shunt is in both directions
Eisenmenger "physiology," i.e., pulmonary hypertension with bidirectional shunt	Depends on site of defect. Commonest is ventricular septal defect when R. V. and P. A. higher than R. A. and V. C.				Unsaturation	In atrial defect, V. C. lower than R. A., R. V. and P. A. In patent ductus P. A. higher than R. V., and brachial artery higher than femoral artery.

Normally the difference in oxygen content between the venae cavae and right atrium is less than 1.9 volumes per cent, between the right atrium and right ventricle less than 0.9 volume per cent, and between the right ventricle and pulmonary artery, less than 0.5 volume per cent.

P. A. = pulmonary artery, R. V. = right ventricle, R. A. = right atrium, V. C. = venae cavae, S. V. C. = superior vena cava, I. V. C. = inferior vena cava.

Table 99. Pressures during Cardiac Catheterization (mm. Hg)

	<i>Venae Cavae</i>	<i>Right Atrium</i>	<i>Right Ventricle</i>	<i>Pulmonary Artery</i>	<i>Pulmonary Capillary</i>	<i>Remarks</i>
Normal	0-5	0-5	18-30/0-5	18-30/6-12 Mean 13-17	6-12	Normal left atrial pressure, 4-8
Patent ductus arteriosus	Normal	Normal	Normal to increased	Normal to increased	Normal to increased	Right atrial and caval pressures increased in congestive failure
Atrial septal defect	Normal	Normal	Normal to increased	Normal to increased	Normal	
Ventricular septal defect	Normal	Normal	Normal to increased	Normal to increased	Normal to increased	Right atrial and caval pressures increased in congestive failure
Anomalous pulmonary veins (partial)	Normal	Normal	Normal to increased	Normal to increased	Normal	
Isolated pulmonary stenosis	Normal to increased	Normal to increased	Increased	Normal to decreased	Normal	Left atrial pressure normal, and right atrial pressure curve may show prominent "a" wave

Eisenmenger physiology	Normal to increased	Normal to increased	Increased	Increased	Normal	

FIG. 248. Typical diagrams of dye dilution curves. T-1824 is injected into the antecubital vein, and photokymographic records of the dilution curve are obtained by oximetric readings of blood from a peripheral artery (e.g., radial artery). The upper curve shows the time components from a normal subject. The middle curve indicates a central right-to-left shunt. Note the decrease in appearance time and the abnormal hump on the build-up slope. The lower curve indicates a central left-to-right shunt. Note that the maximum concentration of dye is less than normal and that the disappearance time is prolonged. The peak concentration of dye is lower in both a left-to-right and a right-to-left shunt. In the majority of instances the indicator dye is injected selectively into specific cardiac chambers or blood vessels, depending on the site of suspected shunt.

oxygen saturation may be determined by analysis of blood obtained by direct puncture of the brachial or femoral artery or by oximetry. Normal arterial blood has an oxygen saturation between 94 and 98 per cent. These levels are reduced in veno-arterial shunts and in disease of the pulmonary epithelium or vasculature which results in failure of proper oxygenation of the blood. The response of arterial oxygen saturation to exercise is a measurable index of the incapacity of the patient. In cyanotic congenital heart disease (e.g., tetralogy of Fallot) the resting arterial oxygen saturation is low; it is further reduced on exercise, and the time taken for recovery to the control level is prolonged.

**Angiocardiography.** The great blood vessels and individual cardiac chambers may be visualized by injection of suitable contrast

media. It appears that venous angiocardiography (i.e., injection of contrast material into a peripheral vein) with serial roentgenograms taken at speeds of two to four per second has little to offer in the diagnosis of cardiovascular malformations. This technique has been superseded by the introduction of selective angiocardiography, i.e., injection of contrast material into specific cardiac chambers or great vessels. This method allows identification of specific abnormalities without the superimposition of the shadows of normal chambers. After contrast material has been injected, serial roentgenograms may be obtained in two planes at a rate of six to fourteen per second.

Image intensification and photofluorography have made possible cardiac catheterization and selective angiocardiography simultaneously. It has the distinct advantage of reducing

radiation to the patient by tenfold to fiftyfold during fluoroscopy. The method has been combined with a closed circuit television which monitors the fluoroscopic screen and allows visualization of the cardiac silhouette and the cardiac catheter without previous dark adaptation. The reaction of the patient to the various phases of the study can be seen because fluoroscopy is performed in a normally lighted room. After the cardiac catheter has been introduced into the specific chamber to be studied a small amount of contrast medium is rapidly injected, and moving pictures are exposed at thirty to sixty frames per second. The technique of recording the movement of contrast medium by motion pictures has been extremely helpful because each examination can be studied repeatedly by running the motion picture at various speeds.

The injection of contrast medium into the circulation is not without hazard and should be used discriminately. Deaths have been reported from iodine sensitivity, cardiac arrhythmia, cerebrovascular complications and pulmonary edema. However, the risk has been reduced by the introduction of better contrast agents. Also, in selective angiocardiology, the amount of contrast medium used is reduced as compared to that for venous angiocardiology.

"Idealized" diagrams of the normal angiogram are shown in Figure 236. The indications for this study are outlined under the individual congenital lesions described later in this section.

**Arteriography.** The aorta and its branches may be outlined by injecting a contrast medium intra-arterially and recording its course by rapid serial roentgenograms or moving pictures. In infants and young children the arterial circulation may be visualized after retrograde injection of dye through a cannula placed in the brachial artery (Keith and Forsyth). In older children and adolescents a catheter may be passed from the brachial artery into the first or second part of the aorta and the contrast medium injected for visualization of the aorta and its branches (Helmsworth and co-workers). This study may be of value in the diagnosis of patent ductus arteriosus, peripheral arterial aneurysms, some instances of coarctation of the aorta and arterial malformations (e.g., the study of the renal vessels in patients with suspected renal hypertension). The indications for arteriography have decreased with the introduction of combined cardiac cath-

terization and selective angiocardiology. The latter techniques allow the diagnosis of these anomalies and also may identify unsuspected associated malformations.

**Roentgenokymograms.** Roentgenokymograms are produced by interposing a slotted cassette between the film and the patient. During continuous exposure to the roentgen rays for about two seconds the film moves downward and records in one picture the variations of the cardiac size during systole and diastole. The excursion of pulsation of the heart and great vessels may also be measured with a photoelectric cell and recorded as a continuous tracing on a moving film. Such procedures provide permanent records of the activity of the heart as observed periodically in the fluoroscope.

**Circulation Time.** The circulation time may be determined by injection of a substance such as saccharin or sodium dehydrocholate in an arm vein and recording the time which elapses until the sensation of the characteristic taste occurs. Histamine, ether and radioactive substances have also been used. A sharp end point may be obtained with a sodium cyanide solution which makes the child gasp when it reaches the aortic body, or with fluorescein, which produces a green fluorescence of the lips when viewed under an ultraviolet lamp. The average time required for circulation of blood (as measured by the fluorescein method) from a peripheral arm vein to the heart through the lungs and finally to peripheral capillaries is about seven seconds in infants and eleven seconds in older children (Witzberger and Cohen). Many of the tests of circulation time depend on subjective sensations which are commonly difficult to evaluate in young patients.

**Phonocardiography.** Sound waves produced by the cardiac tones and murmurs may be recorded simultaneously with electrocardiographic and pulse waves. By this method the time at which murmurs occur in the cardiac cycle may be determined more accurately, and their duration, shape and other properties may be measured, and permanent records are provided.

**Arteriogram and Phlebogram.** Recordings of the arterial pulsations from a peripheral vessel may be obtained directly from an indwelling needle or indirectly by recording the movement of an expansile capsule over the surface of the artery. The former method is more accurate and is preferable. Most abnormal contours can be discerned by the palpating finger, but records of the peripheral

arterial wave are also helpful. Details of the peripheral venous pulsations (phlebogram) have already been described.

**Vital Capacity.** The amount of air which can be forcibly expired after a maximum inspiration represents the vital capacity and may be recorded on a spirometer. The capacity of a normal child is computed in terms of his age, height, weight or square meter of body surface. The results vary widely in young children, but repeated tests in the same child provide evidence of progress of his disease over a period of time.

**Standard Exercise Test.** The objective of this test is recognition of mechanical obstruction in the outflow tract of the right ventricle or in the pulmonary valve. In a normal person the pulmonary circulation increases sufficiently to meet the respiratory demands of exercise, and there is an increase in the ratio of oxygen consumed to the liters of ventilation. In patients with pulmonary stenosis mechanical obstruction limits the pulmonary blood flow, and the ratio falls. The standard exercise test, in which the patient steps up and down on a 20-cm. step thirty times in one minute, is positive in about 75 per cent of patients with pulmonary stenosis.

**Response to exercise.** Various tests have been devised to evaluate myocardial function. These tests depend on the response of the pulse and respiratory rates and variations in the level of blood pressure to a specific exercise (Master, Schneider). It is usually difficult to evaluate these results because they depend on the cooperation of the patient. The wide variation in results obtained in normal children must be borne in mind when patients with cardiac disease are tested. Fine grades of differences in myocardial function are not detectable by these methods.

The presence of *external dyspnea* is frequently difficult to ascertain in young patients, especially those with acyanotic congenital heart disease. Parents may deny the symptom of exercise intolerance and only appreciate the previous incapacity of the child when his activity has increased to normal after surgical therapy. In infants one of the early signs of dyspnea on exertion is manifest during feeding, since it is not possible to breathe and swallow simultaneously.

**Ballistocardiography.** Recoil of the body in the opposite direction to the ejection of blood from the heart may be recorded graphically if the subject is placed on a suitable table (Starr). Small tables for children have

been constructed to record body movements in "head-to-foot" and "side-to-side" directions. Coarctation of the aorta is associated with an absent or small K wave.

## CONGENITAL HEART DISEASE

**Fetal Circulation.** During fetal life, blood flows from the fetus by way of the umbilical artery to the placenta, where it exchanges carbon dioxide and other waste products for oxygen and nutritive material. The oxygenated blood returns to the fetus through the umbilical vein; part of it goes directly into the inferior vena cava by way of the ductus venosus, and the remainder passes through the liver on its way to the heart. The blood entering the heart from the inferior vena cava is therefore a mixture of oxygenated and deoxygenated blood. The blood from the

superior vena cava passes directly to the right ventricle through the tricuspid orifice, while the blood from the inferior vena cava divides into two streams, one directed into the right ventricle and the other through the open foramen ovale into the left atrium. In this way a part of the blood entering the right atrium is shunted directly to the left atrium and ventricle and out through the aorta without passing through the lungs. The blood which enters the right ventricle is directed toward the lungs, but, since the lungs are not expanded, most of it is shunted into the

FIG. 249. Plan of the human circulation before birth (partly after Dodds). Colors show the quality of the blood, and arrows indicate its direction of flow (Arey).

aorta by way of the ductus arteriosus, which connects the pulmonary artery and aorta. Thus the blood in the aorta which circulates to all parts of the body is a mixture of partly oxygenated and deoxygenated blood. A portion flows by way of the hypogastric arteries to the umbilical arteries and then to the placenta (Fig. 249).

**Circulation in the Newborn Infant.** Changes in circulation occur rapidly after birth. When the cord is clamped and the lungs expand, the pulmonary circulation increases greatly in volume. The foramen ovale, the ductus arteriosus and ductus venosus are no longer needed, but their closure proceeds gradually. The foramen ovale is functionally closed by the third month of life, although it is possible to pass a probe through the overlapping flaps in 25 per cent of adults (Patton). In the studies of Christie the ductus was closed in 88 per cent of infants by the end of the eighth week, and the foramen ovale was closed in 87 per cent of infants by the end of the twelfth week. During this

period of adjustment there are rarely physical signs of patency of these structures. On rare occasions emboli to the abdominal aorta and its branches (especially mesenteric) may arise from thrombosis in the ductus arteriosus.

**Incidence of Congenital Heart Disease.** The two important conditions which produce cardiovascular diseases in children are congenital heart disease and rheumatic fever. The introduction of antimicrobial agents for the treatment and prophylaxis of streptococcal infections has resulted in a large decrease in the incidence of acute rheumatic fever within the last decade. Simultaneously great advances have been made in the diagnosis and surgical treatment of congenital cardiovascular diseases. In centers where diagnostic and surgical facilities are available new patients with congenital heart disease are almost ten times more frequent than those with acute rheumatic fever.

MacMahon found an incidence of congenital heart disease of about three per 1000 at birth and one per 1000 at the age of ten

years. In a study of 60,000 infants Richards and her associates found that 0.83 per cent had congenital heart disease. Cardiovascular malformations account for about 50 per cent of the deaths caused by congenital defects in the first year of life. It is difficult to establish the frequency of various lesions from published reports because these data depend on the source of the material, e.g., the age of the patient and whether the study was based on pathologic or clinical material (Table 100).

**Etiology.** *Maternal disease* influences the bodily structures of the fetus. German measles in the mother during the early weeks of pregnancy may interrupt development of the fetus with resulting deformities of the heart, eyes, ears and other tissues. The offspring of rats maintained on diets deficient in vitamin A often have defects of the heart and great vessels as well as of other structures (Warkany and Wilson). It seems possible that other infections and nutritional disorders of the mother may be factors causing congenital heart disease.

The role of *heredity* as an etiologic factor is not understood. Congenital heart lesions are recorded in two and even three generations of a family (Taussig); Abbott observed congenital heart disease more frequently in sibships than in their preceding or succeeding generations. From the data available it would seem unwise to discourage parents of

a child with congenital heart disease from having additional children.

The *incidence of other congenital defects* among patients with congenital heart disease is apparently greater than among those with normal hearts. Mongolism is frequently associated with persistent atrioventricular canal or ostium primum defects. Coarctation of the aorta occurs in Turner's syndrome. Diseases of the aorta and the aortic valve occur frequently in Marfan's syndrome and may result in dissecting aneurysm of the aorta in adult life. Cataracts, deafness and skeletal defects have been noted with increasing frequency in patients with congenital cardiac lesions. Among the 1000 patients with congenital heart disease reported by Abbott, 188 patients had anomalies elsewhere in the body, and Vierordt noted that 80 of a group of 700 patients with congenital heart disease had multiple congenital lesions. A knowledge of the types of defects which tend to occur in combinations may help in diagnosis and in a better understanding of the etiologic factors.

**Diagnosis of Congenital Heart Disease.** The development of surgical procedures effective for certain of the congenital cardiovascular defects has made it incumbent to make as accurate a diagnosis as possible. Most often the diagnosis can be established from the history, physical findings and customary roentgenographic and electrocardi-

Abbott's series is based on 1000 autopsies, Wood's on 200 clinically studied cases, Nadas' on 577 cases (clinical and autopsy), and Ober and Moore's on 100 autopsies in infants dying in the first month of life.

ographic examinations. When doubt exists, cardiac catheterization, angiocardiology and aortography often supply the necessary confirmatory information. The greatest difficulty is encountered in young infants and children suffering from such severe circulatory failure that intricate diagnostic procedures might threaten life.

**Classification of Congenital Heart Disease.** Abbott established the custom of dividing congenital heart diseases into two groups: (1) those with cyanosis at rest, and (2) those without cyanosis or who manifest it only under certain adverse conditions, e.g., high pulmonary resistance. Taussig makes a similar division on the basis of malformations which do or do not permit an adequate supply

of oxygen to the body. This classification has been criticized, and other more complicated ones have been suggested; they depend on hemodynamic and anatomic factors, including the direction of shunt. In congenital heart disease persistent cyanosis is usually caused by the shunting of venous blood from the right to the left side of the heart, so that it passes into the systemic circulation without being oxygenated in the lungs. In this text the following classification of the more common anomalies will be used: (1) right-to-left shunts (i.e., with cyanosis), (2) left-to-right shunts (i.e., without cyanosis), (3) no shunt at all. It is appreciated that there is overlapping in these groups.

## CONGENITAL CARDIAC DISEASE WITH CYANOSIS (DOMINANT RIGHT-TO-LEFT SHUNT)

### TETRALOGY OF FALLOT

The combination of (1) pulmonary stenosis, (2) ventricular septal defect, (3) dextroposition of the aorta, and (4) right ventricular hypertrophy constitutes the tetralogy of Fallot. It is the most common condition accompanied by persistent cyanosis and accounts for 75 per cent of cyanotic congenital heart disease in patients over the age of one year. The most common site of stenosis is in the outflow tract of the right ventricle (infundibular), but not infrequently it is valvular or both infundibular and valvular (Brock). The outflow tract of the right ventricle and pulmonary artery are usually smaller than normal. The ventricular septal defect is located in the membranous portion of the ventricular septum in close proximity to the aortic valve. Dextroposition of the aorta indicates that its root is displaced to the right, so that it appears to override both ventricles. The aorta, which is usually large, has a right-sided arch in 20 to 25 per cent of cases (Taussig). A persistent left superior vena cava has been described in 20 per cent (Wood).

**Hemodynamics.** Systemic venous return to the right atrium and right ventricle is normal. When the right ventricle contracts, it meets resistance at the pulmonary stenosis and shunts some of its blood across the ventricular septal defect into the aorta. This results in persistent arterial unsaturation and cyanosis. The pulmonary blood flow is re-

stricted by the obstruction at the pulmonary valve, but may be supplemented by bronchial collateral circulation and occasionally by a patent ductus arteriosus. The systolic and diastolic pressures in each ventricle are similar, as well as the mean pressures in the atria. A measurable gradient of pressure is always detected across the outflow of the right ventricle, owing to the pulmonary stenosis.

It appears that the two major defects in the tetralogy of Fallot are the pulmonary stenosis and the ventricular septal defect. When these conditions exist without right-to-left shunt, the anomaly has been termed *acyanotic Fallot* (see *Pulmonary Stenosis with Ventricular Septal Defect*, p. 870).

**Clinical Manifestations.** *Cyanosis*, one of the outstanding manifestations of the tetralogy, may not be present at birth. It appears that as long as the ductus arteriosus remains open, sufficient blood passes through the lungs to prevent cyanosis. As it closes during the first months of life, cyanosis may become apparent gradually or develop suddenly when the infant has an infection. The cyanosis is most prominent in the mucous membranes of the lips and mouth and in the fingernails and toenails, but the entire skin surface has a dusky, bluish color. The scleras are gray, and the blood vessels at the periphery are likely to be engorged, giving the appearance of a mild conjunctivitis. The blood vessels of the retina are large and dark. The mucous membranes of the pharynx

are purple, and the tongue is deep blue and often large and fissured, with prominent papillae. The gums are frequently inflamed and bleed easily from light pressure. The teeth are normal in size and shape, but their eruption may be delayed; histologic examination reveals dilatation and engorgement of the capillaries in the dental pulp and poor calcification of the dentin. *Clubbing* of the ends of the fingers and toes is a conspicuous sign; the underlying bone may be involved. *Hemoptyses* may be recurrent, some of which may be due to thromboses of the smaller pulmonary arteries.

*Dyspnea* occurs on exertion. Infants and young children will play actively for a short time and then sit or lie down. Older children may be able to walk a block or so before stopping to rest; many of them rest by *squatting* for a few moments or by sitting with their feet elevated. The capacity for exercise depends on the severity of the cardiac lesion, which is often reflected by the intensity of the cyanosis. Young children may have syncopal attacks lasting for a few moments to a few hours after exercise or emotional excitement, possibly the result of cerebral anoxia. The child usually learns his capacity for exertion, and these attacks occur less often with advancing age.

*Paroxysmal dyspneic attacks* are a particular problem during the first two years of life. They may occur spontaneously or follow feeding or a spell of crying. The child becomes dyspneic and intensely cyanotic, cries weakly or loudly as if in pain and may soon lose consciousness, with or without convulsions. Some infants have been noted to clutch or scratch over the anterior chest as if they had precordial pain, somewhat reminiscent of hypercyanotic angina pectoris of older patients. The attacks may last from a few minutes to several hours and are occasionally fatal. Spontaneous recovery from these attacks is followed by deep sleep for a few hours. Depending on the frequency and severity of the attacks, one or all of the following procedures should be tried in sequence: (1) placement of the infant on his abdomen in the knee-chest position, making certain that there is no constricting clothing; (2) administration of oxygen; (3) injection of morphine in doses of 1 mg. per 10 pounds of body weight; this is especially effective.

*Growth and development* may be delayed. The stature and nutritional status are usually below the average for the age, and the

muscles and subcutaneous tissues are flabby and soft. Puberty is delayed.

The *pulse* is usually normal, as are the venous and arterial pressures. The left anterior chest may bulge forward. The heart is usually normal in size, and the apical impulse is tapping in nature. A *systolic thrill* is felt in 50 per cent of cases along the left sternal border in the third and fourth parasternal spaces. Owing to the pulmonic stenosis, the normal pulmonary artery pulsation in the second left interspace is commonly absent.

The *systolic murmur* heard along the left sternal border is usually loud and harsh, and maximal in the third and fourth left parasternal spaces. The systolic murmur is an ejection type and finishes before the aortic element of the second sound. The second sound at the base is single, owing to the absence of the pulmonary element. In a small number of cases the systolic murmur may be followed by a blowing diastolic murmur heard over any part of the precordium or in the back between the scapulae. This diastolic murmur is produced by enlarged bronchial collateral vessels and rarely by persistence of a patent ductus arteriosus, but occurs most frequently in pulmonary atresia.

*Polycythemia* and an elevated *hematocrit* value are usual. The defects in coagulation have been described (p. 831).

The *exercise test* devised by Bing demonstrates that there is no increase in oxygen consumption per liter of ventilation during exercise. This test, positive in about 75 per cent of cases, suggests the presence of pulmonary stenosis, which prevents an adequate increase of the pulmonary circulation during exercise.

**Roentgen Examination.** The typical configuration in the anteroposterior position consists of a narrow base, concavity of the left border in the area usually occupied by the pulmonary artery and a normal heart size. The rounded apical shadow situated rather high above the diaphragm is produced chiefly by the hypertrophied right ventricle and has been likened to the shape of a sheep's nose; the entire cardiac silhouette, to that of a wooden shoe (*coeur en sabot*) (Fig. 250). In the right anterior oblique view the configuration is accentuated. The shadow of the large right ventricle approaches and may touch the anterior chest margin, and there is a deep concavity immediately above it where the pulmonary artery is usually seen in the normal patient. In the

FIG. 250. Teleroentgenogram of a patient with tetralogy of Fallot. Note the pulmonary undervascularity, normal heart size, elevation of the apex of heart and a concavity in the region of the main pulmonary artery.

left anterior oblique view the right ventricle tends to encroach upon the anterior chest wall, the left ventricle may be clear of the vertebral column, and the pulmonary window is clear. In many patients the hypertrophied right ventricle displaces the normal left ventricle posteriorly so that the latter chamber partly overlies the spine.

The aorta is usually large, and its position is important. In about 20 per cent of instances the aorta arches to the right instead of the left; this may be clearly visible in the anteroposterior view or may be confirmed by displacement of the barium-filled esophagus to the left. In the left oblique view a right aortic arch may indent the esophagus.

The hilar areas of the lungs are relatively clear and usually pulsate little or not at all, owing to the absence of normal pulmonary vessels. The lung fields are remarkably clear for the same reason; this constitutes an important diagnostic sign which may be detected either by fluoroscopy or in roentgenograms.

Variations from the typical radiographic picture include exaggeration of the shadow of the pulmonary artery usually associated with valvular pulmonic stenosis (Fig. 251). Occasionally pulmonary vascularity is made prominent by a reticular pattern of collateral bronchial circulation which radiates from the hilus of the lungs (Fig. 252). In the oblique projections the right ventricular shadow may be normal or recede in a manner suggestive of an underdeveloped right ventricle. The electrocardiogram is much more accurate in

the assessment of ventricular dominance than is the roentgenographic examination.

**Electrocardiography.** The electrocardiogram reveals evidence of right ventricular hypertrophy, clockwise rotation and often tall, spiked P waves. Evidence of right ventricular dominance, without which the diagnosis of tetralogy of Fallot is unlikely, is found in the right precordial chest leads and in the unipolar right arm lead (Figs. 239, 240).

**Other Tests.** In the majority of instances the diagnosis of tetralogy of Fallot can be made with the aid of the foregoing studies, but doubtful cases would require cardiac catheterization or angiocardiology to help elucidate the anatomic anomalies.

**Cardiac catheterization** reveals systolic hypertension in the right ventricle and a sudden fall of pressure as the catheter enters the infundibular chamber or pulmonary artery. Serial pressure determinations taken from the region of stenosis of the right ventricular outflow tract may in some instances differentiate between valvular and subvalvular stenosis. In valvular stenosis the change in pressure from the pulmonary artery to the right ventricle is abrupt, whereas in infundibular stenosis the change is less abrupt, but may show three pressure differentials as the catheter tip is withdrawn from the pulmonary artery, the infundibular chamber and right ventricle, respectively (Fig. 253). The systolic pressure in the right ventricle is

FIG. 251. One of the variants in the teleroentgenogram in tetralogy of Fallot. The stenosis was localized to the pulmonary valve, and poststenotic dilatation of the pulmonary artery is evident. The intrapulmonary vascularity is decreased.

usually between 60 and 90 mm. of mercury.

The mean pulmonary artery pressure is commonly between 5 and 10 mm. of mercury, and the right atrial pressure is usually normal. The aorta may be entered from the right ventricle through the ventricular septal defect (Fig. 247, I). Samples of blood from the venae cavae, right atrium, right ventricle and pulmonary artery are frequently similar in oxygen content, indicating absence of a left-to-right shunt. In many patients, how-

ever, a left-to-right shunt is demonstrated at the ventricular level (Table 98).

*Selective angiocardiology* is of great value. The injection of contrast material into the right ventricle demonstrates the outflow tract and identifies the site of stenosis. The presence and location of infundibular and/or valvular stenosis are clearly visualized, and their behavior can be studied during systole and diastole. Simultaneous opacification of the aorta by the passage of contrast medium

FIG. 252. Aortogram in tetralogy of Fallot demonstrating the possible collateral circulation to the lung. A, The thoracic and abdominal aorta and their branches are visualized. The left pulmonary artery fills from a patent ductus arteriosus. The right pulmonary artery is absent, and the right lung is supplied by a large bronchial artery arising from the third intercostal artery. This patient had a gratifying clinical improvement after a left Blalock-Taussig operation. B, Same aortogram as in A. The details of the descending thoracic aorta, left pulmonary artery and large bronchial artery are demonstrated.

FIG. 253. Pressure curve obtained during cardiac catheterization in a patient with combined valvular and infundibular pulmonary stenosis and a ventricular septal defect. The upper tracing is the electrocardiogram. The lower tracing is a continuous record of pressure as the catheter was withdrawn from the pulmonary artery to the right ventricle. Three pressure differentials are noted, corresponding to the pulmonary artery, infundibular chamber and right ventricle. The right ventricular pressure is higher than that in the infundibular chamber and pulmonary artery and indicates the presence of pulmonary stenosis. Infundibular stenosis is recognized because the diastolic pressure in this area is lower than that in the pulmonary artery and the same as in the right ventricle. In many patients the systolic pressure in the infundibular chamber exceeds the pulmonary artery systolic pressure, but is lower than the right ventricular systolic pressure.

FIG. 254. Selective cine-angiogram in a patient with tetralogy of Fallot. Film speed is 60 frames per second. The tip of the catheter is in the right ventricle, and the patient is in the left posterior oblique projection. The contrast medium in the lower right of each frame is in the cavity of the right ventricle. A constant obstruction to the outflow of the right ventricle is seen anteriorly, and the infundibular chamber is visualized. Simultaneous opacification of the aorta from the right ventricle is confirmed by the presence of contrast medium in the descending aorta anterior to the vertebral column.

through the ventricular defect is also clearly identified.

The *circulation time* from arm to tongue is shortened because the blood entering the right ventricle is shunted into the systemic circulation through the overriding aorta.

**Prognosis.** Without operation the prognosis varies with the severity of the pulmonary stenosis and the amount of collateral circulation. Deeply cyanotic children who have dyspnea on slight exertion rarely live until late childhood. Others may succumb during the adolescent period, and a few may live beyond the third decade. In early childhood fainting and paroxysmal dyspnea may occur after exertion or excitement. Some children die in such attacks; anoxia or thrombosis of a vessel in a vital organ, usually the brain, may be the terminal event. The incidence of a variety of disorders is higher than in average children; these include pulmonary tuberculosis, pyogenic respiratory infections, pulmonary artery thromboses, sub-

acute bacterial endocarditis and brain abscess. Congestive heart failure is unusual.

**Treatment. General management.** Although the majority of patients require surgical treatment, astute management is necessary prior to surgery. The prevention or prompt treatment of dehydration is important to avoid hemoconcentration and possible thrombotic episodes. The treatment of paroxysmal dyspneic attacks has been described (p. 843). Intercurrent infections should be vigorously treated with suitable antibiotics. Nadas and Rudolph have shown that correction with iron therapy of a "relative hypochromic anemia" may improve the exercise tolerance and general well-being. It appears that the safest level of the hematocrit is between 55 and 65 per cent. Cautious repeated venesection may be indicated if the hematocrit value is above 70 per cent, because at this level there is a high incidence of thromboses, especially cerebral.

**Surgical. ANASTOMOTIC PROCEDURES.** Taussig observed that the prognosis was better when the ductus arteriosus was patent. She and Blalock devised the operation whereby an artificial ductus is created by anastomosis of a branch of the aorta to the homolateral branch of the pulmonary artery. The most common procedure is an end-to-side anastomosis of a subclavian artery to the pulmonary artery. Potts and his associates achieved the same objective by side-to-side anastomosis of the aorta to the pulmonary artery.

There are no rigid criteria for choosing between a Blalock-Taussig or Potts procedure. In the former the inner opening of the anastomosis depends on the inner diameter of the subclavian artery, whereas in the Potts procedure the size of the side-to-side anastomosis does not depend on the caliber of the vessels and therefore may be preferable in children under the age of two or three years. If the aorta arches to the right, the Potts procedure is not technically possible. When tetralogy of Fallot is associated with dextrocardia, the vessels for anastomosis should be identified by angiocardiography, and the operation of choice would depend on the relationship of these arteries. During the Potts procedure mobilization of the aorta may require sacrificing precious bronchial vessels, which would be undesirable in patients in whom a large bronchial collateral flow is suspected.

The *operative risk* varies with the age of

the patient, the mortality rates being higher in infants and adults. The best results are obtained in children between the ages of two years and puberty. However, if incapacitating symptoms occur before the age of two years, operation is urgently indicated. The surgical mortality rate in patients between the ages of two and twelve years is less than 5 per cent, whereas in infants and adults the rate may be as high as 20 per cent.

The *postoperative course* of 90 per cent of patients with a successful anastomosis is smooth, and the child should be ambulatory within three to seven days. In addition to the usual postoperative complications following a thoracotomy, chylothorax, Horner's syndrome and postoperative cardiac failure may occur. Chylothorax is due to trauma to the thoracic duct or its tributaries and is treated with repeated thoracenteses. Horner's syndrome is usually temporary and does not require treatment. Postoperative cardiac failure may be due to the large size of the anastomosis; its treatment is described on page 897. Other rare complications include endothelialization of the anastomotic site with the obstruction of blood flow, subacute bacterial endarteritis and vascular changes in the upper extremity supplied by the subclavian artery which has been used for anastomosis.

After a successful anastomosis there is a striking improvement in symptoms. Exercise tolerance is increased, and the habit of squatting is discontinued. The degree of cyanosis and clubbing diminishes. A machinery-type murmur, sometimes accompanied by a thrill, is detected after operation. This murmur is indicative of a functioning anastomosis and is permanent.

**BROCK PROCEDURE.** Brock has suggested a direct surgical attack on the pulmonary stenosis by pulmonary valvotomy if the stenosis is valvular, or infundibular resection if the outflow tract of the right ventricle is stenosed. With these procedures about two thirds of patients are greatly improved, one sixth are benefited and nearly one sixth die, the mortality rate being higher with infundibular resection (Campbell, Deucher and Brock).

**DIRECT-VISION INTRACARDIAC SURGERY (WITH A PUMP OXYGENATOR).** Theoretically, the ideal surgical therapy is relief of pulmonary stenosis and closure of the ventricular septal defect. This form of therapy is now being utilized with the aid

of a pump oxygenator. While the patient's circulation is temporarily maintained by an artificial heart-lung machine, the right ventricle is opened extensively, the infundibular stenosis resected, coexistent valvular pulmonary stenosis is relieved, and the ventricular septal defect is closed. If indicated, the outflow tract of the right ventricle is enlarged by placing a plastic prosthesis anteriorly at and below the pulmonary valve.

**CHOICE OF SURGICAL PROCEDURE.** Before parents can be advised which of the foregoing procedures should be undertaken for the child, the physician must be aware of the immediate surgical risks as well as the expected long-term results. It has been pointed out that operative risk with the anastomotic procedures is low and the immediate clinical improvement gratifying. However, some incapacity frequently remains, and, although cyanosis, clubbing and polycythemia are greatly reduced, they are seldom abolished. Some years after the anastomosis the clinical condition may deteriorate, requiring a second anastomosis, on the opposite side. A complication which is now becoming apparent is the development of severe pulmonary hypertension many years after the anastomosis was made.

The Brock procedure has a higher mortality rate than the anastomotic operation, but the immediate clinical improvement is better, especially after infundibular resection. Adequate relief of pulmonary stenosis leaves the patient with a ventricular septal defect which in later years may result in severe pulmonary hypertension and heart failure.

There appears to be little doubt that the theoretic procedure of choice is direct-vision, open heart surgery. This results in relief or improvement of the pressure gradient from the right ventricle to the pulmonary artery and abolishes the right-to-left shunt across the ventricular septal defect. In successful cases the results are spectacular with disappearance of symptoms and signs of anoxia. However, at this time, the mortality rate is still high (10 to 30 per cent), the lower mortality rate comprising selected cases. Further, sufficient time has not elapsed for evaluation of long-term results. It may be argued that anastomotic procedures could be used as temporizing therapy while the results of the direct approach are being improved and evaluated. However, the risk of surgery with the pump oxygenator may be higher if a patient has had a previous thoracotomy.

Therefore at present the choice of the surgical procedure is still not clear, but direct-vision surgery holds the most promise.

### PULMONARY ATRESIA

Complete obliteration of the main pulmonary artery and the pulmonary valve is always associated with a ventricular septal defect and usually with dextroposition of the aorta. The hemodynamics are similar to those of tetralogy of Fallot except that the pulmonary blood flow is dependent on the bronchial collateral flow or, in some instances, on a large patent ductus arteriosus.

The *clinical manifestations* are much the same as those of the tetralogy with the following exceptions: Cyanosis usually appears within a few days after birth in contrast to later in the first year in the tetralogy. The systolic murmur is absent or is softer and is not characteristic. The second sound at the base is moderately loud and never split. Continuous murmurs due to bronchial collateral flow may be heard anywhere in the chest, anteriorly or posteriorly, but are usually heard best under the clavicles. The heart may be enlarged, and the deep indentation of the left border is the same as that produced by the tetralogy. The reticular pattern of the bronchial collateral flow is shown roentgenographically.

The diagnostic study of choice is *selective angiocardiology* with injection of contrast medium into the right ventricle. Although the main pulmonary artery is atretic, its two primary branches may be of sufficient caliber to allow an anastomotic procedure. Either the left or the right pulmonary artery may be absent in association with other defects of tetralogy of Fallot. This is suspected when the pulmonary vascularity is heavy on one side and decreased on the other. These patients can be benefited by a Blalock-Taussig anastomosis on the side of the pulmonary artery.

### TRICUSPID ATRESIA

Atresia or stenosis of the tricuspid valve is accompanied by underdevelopment of the right ventricle and pulmonary stenosis or atresia. Little or none of the blood entering the right atrium can gain access to the right ventricle and must escape to the left atrium by way of the foramen ovale or a gross defect in the interatrial septum. In the left atrium the mixture of blood passes into the left

FIG. 255. Teleroentgenogram in tricuspid atresia with underdeveloped right ventricle (see text).

ventricle, and through the aorta to the systemic circulation. The pulmonary circulation is derived from the systemic blood, which reaches the lungs either through a ventricular septal defect, patent ductus arteriosus or enlarged bronchial arteries.

**Clinical Manifestations.** Cyanosis, polycythemia, exertional dyspnea and anoxic hypercyanotic (paroxysmal dyspneic) attacks develop early. After infancy, clubbing and squatting are usually present. Owing to the tricuspid stenosis, the pressure in the right atrium is increased, resulting in a prominent jugular venous "a" wave. In a similar way, the liver is frequently enlarged and may exhibit an intrinsic presystolic pulsation. The heart may or may not be enlarged with a heaving left ventricular apical impulse. In very ill small infants, murmurs may not be prominent, but in the majority of instances a harsh systolic murmur is audible maximally down the left sternal border. The second heart sound is single, owing to absence of the pulmonary element.

*Roentgenographic studies* demonstrate pulmonary undercirculation and deficiency of shadows of the pulmonary artery segment (Fig. 255), but the shape of the cardiac silhouette is not always distinctive and in some cases may resemble that of tetralogy of Fallot. Although the right ventricle is small, its shadow may or may not be decreased in the oblique projections. In fact, the positional displacement caused by the hypertrophied left ventricle may produce a radiologic picture of an enlarged right ventricle.

The *electrocardiogram* is a much more

sensitive index of the state of the ventricles. In normal infants a prominent R wave in the right ventricular surface leads is produced by a summation of the electrical activity of the interventricular septum and right ventricle. In tricuspid atresia with underdeveloped right ventricle the r wave in the right ventricular surface leads is produced by activation of the interventricular septum only and is therefore small and is followed by a deep S wave. Left ventricular dominance is suggested by S-T segment and T wave abnormalities in the left ventricular surface leads. The electrical position is also unusual in these patients, and aVR commonly shows a Q-S pattern. The heart is commonly horizontal, but may on occasion be vertical. The P waves are usually tall and spiked.

*Cardiac catheterization* shows an elevated right atrial pressure with a prominent "a" wave in the pressure curves taken from the right atrium and cavae. If the catheter is introduced from the saphenous vein into the inferior vena cava and right atrium, it usually passes with ease across the foramen ovale or atrial septal defect into the left atrium or pulmonary veins (Fig. 247, C, E.).

With *selective angiocardiology* there is immediate opacification of the left atrium from the right atrium followed by left ventricular filling and visualization of the aorta (Fig. 256). The pulmonary artery or its branches may be demonstrated because these

structures receive blood from a patent ductus arteriosus or from the left ventricle across a ventricular septal defect. On occasion the diminutive right ventricular chamber is visualized.

**Prognosis and Treatment.** The prognosis is poor, and many infants fail to survive the first few months of life unless collateral circulation to the lungs is adequate. Improvement may occur from anastomosis of the aorta or one of its branches to the pulmonary artery, but the results are not as gratifying as with the treatment of tetralogy of Fallot. Disappointing postoperative results may occur, owing to inadequacy of the defect between the atria or because of left ventricular failure. With good results the postoperative clinical course is similar to that described under Tetralogy of Fallot (p. 847).

### EISENMENGER SYNDROME

The term "Eisenmenger syndrome" is used here for the combination of pulmonary hypertension with reversed shunt either through a ventricular septal defect, atrial septal defect or patent ductus arteriosus (or other communications between the aorta and lesser circulation). This concept implies that the major physiologic abnormality is elevation of the pulmonary vascular resistance. In normal infants at, or soon after, birth the pulmonary vascular resistance is high, probably owing

FIG. 256. Angiogram in tricuspid atresia with underdeveloped right ventricle. A, 1.5 seconds after injection of contrast medium. The contrast substance has opacified the right atrium and passed across an atrial septal defect into the left atrium and left ventricle. B, 2 seconds after injection of contrast medium. Note opacification of the aorta and its branches and the pulmonary artery. The right ventricle was not visualized.

FIG. 257. Teleroentgenogram in Eisenmenger syndrome due to a ventricular septal defect. Note the dilatation of the pulmonary artery and gross pulmonary overvascularity.

to relatively small lumens of the arterioles. Within a few months the structure of the pulmonary arterioles changes to that of the adult pattern with a thin wall and a large lumen, and the pulmonary vascular resistance falls to normal adult levels. In the Eisenmenger syndrome the pulmonary vascular resistance remains high; this abnormal resistance is probably present from birth (Edwards, Dammann).

**Clinical Manifestations.** Symptoms are usually present within the first year of life, especially in patients with ventricular septal defect. These include dyspnea, feeding difficulties, fatigue, failure to gain weight and recurrent attacks of pneumonia. As the child gets older effort dyspnea is obvious, especially when there are ventricular and atrial septal defects. Squatting, angina pectoris, hemoptysis and episodes of syncope occur occasionally. Cyanosis, which may be present early, increases in intensity as the child approaches puberty and is associated with clubbing and polycythemia. In patent ductus arteriosus, venous blood from the pulmonary artery is shunted down the descending aorta. This may result in differential cyanosis (blue lower extremities and pink upper extremities), but this sign is not common in children.

The venous pressure is increased when congestive heart failure or functional tricuspid insufficiency is superimposed. The heart size is extremely variable, being normal in many cases with ventricular defect, but usually enlarged with atrial defect. A conspicu-

ous left parasternal, right ventricular heave with palpable pulmonary artery pulsations is frequent. Although a systolic murmur is usual, it varies in intensity, but there may be none. The second heart sound is closely split or single in many cases of ventricular defect, but is widely split in atrial defect. Functional incompetence of the pulmonary valve (Graham Steell murmur) resulting in a blowing diastolic murmur down the left sternal border is common and is associated with a normal peripheral pulse.

*Roentgenographically*, the heart is found to vary in size from normal to greatly enlarged. The larger hearts are seen with atrial defects and the smaller ones with ventricular defects, but there is a large overlap. The pulmonary artery is usually enlarged. The pulmonary vessels are enlarged in the hilar areas and diminish in caliber in the peripheral branches. The right ventricle and atrium are prominent.

The *electrocardiogram* frequently shows right ventricular hypertrophy, occasionally associated with incomplete right bundle branch block. The P wave may be tall and spiked. Sometimes the electrocardiogram is balanced and does not reveal the ventricular hypertrophy.

*Cardiac catheterization* usually shows a bidirectional shunt at the site of the defect; e.g., in patients with a ventricular septal

FIG. 258. Teleroentgenogram in Eisenmenger syndrome due to a patent ductus arteriosus. The heart size is normal, the pulmonary artery segment is dilated, and the pulmonary vascularity is normal or slightly increased.

defect a left-to-right shunt is demonstrated at the ventricular level and is associated with a decrease in the arterial oxygen saturation due to the right-to-left shunt. There is, of course, a definite decrease in arterial oxygen saturation when there is only a right-to-left shunt. The catheter frequently traverses the defect, especially in patent ductus arteriosus and in atrial septal defect. The systolic pressures are usually equal in the systemic and pulmonary circulations. The pulmonary vascular resistance is elevated. *Dye dilution curves* demonstrate the bidirectional shunts or the unidirectional right-to-left one. *Selective angiocardigraphy* is helpful in locating the site of the shunt. In patent ductus arteriosus contrast medium enters the descending aorta from the pulmonary artery.

**Treatment.** The presence of the Eisenmenger syndrome contraindicates surgical closure of the defect. The results of attempts at surgical correction have most often been disastrous. However, it should be understood that pulmonary hypertension with increased pulmonary blood flow, but without a right-to-left shunt, is not the Eisenmenger syndrome and does not contraindicate surgery. In these patients surgery is lifesaving. Medical treatment of the Eisenmenger syndrome is entirely symptomatic.

### TRANSPOSITION OF THE GREAT VESSELS (ARTERIES)

In this condition the aorta arises from the right ventricle and the pulmonary artery from the left ventricle. The systemic veins return to the right atrium, and the pulmonary venous return is to the left atrium. Thus the blood from the right side of the heart passes to the aorta. The pulmonary venous blood is returned to the lungs. The two independent circuits do not support life unless the foramen ovale or the ductus arteriosus remains open or unless there is a defect in the atrial or ventricular septum to permit some mixture of blood. This condition accounts for the majority of deaths in infants under the age of one year with cyanotic congenital heart disease (Ober and Moore).

**Clinical Manifestations.** Dyspnea, retardation of growth and signs of congestive heart failure are frequent. Cyanosis makes its appearance shortly after birth. Differential cyanosis occurs in some patients in whom the lower extremities are less cyanotic than the rest of the body. The difference in color may be obvious if the child's hand is placed by

the side of his foot. This difference is due to patency of the ductus arteriosus and not uncommonly is associated with coarctation of the aorta above the entry of the ductus. Because the pulmonary artery pressure may be higher than that of the descending aorta, oxygenated blood enters the aorta from the ductus and is carried only to the lower part of the body. Anoxic, paroxysmal dyspneic attacks may occur, but not as frequently as in the tetralogy of Fallot. Murmurs are of no diagnostic significance and are absent in about 30 per cent of cases in early life. If present, the murmur is usually systolic in time and is heard over most of the precordium. The second heart sound is split. Polycythemia and arterial unsaturation are usual.

*Roentgenograms* reveal that, although the heart is enlarged, the base is comparatively narrow in the anteroposterior view, because the aortic shadow is superimposed upon that of the pulmonary artery segment (Fig. 259). In the left anterior oblique position both ventricles are found to be enlarged, and the great vessels, now lying side by side, greatly increase the basal shadows. The pulmonary vascularity is usually grossly increased. These characteristics may not appear in the early days of life, especially if the basal shadows are obscured by the thymus.

In *electrocardiograms* there is clockwise rotation, right ventricular hypertrophy and, not uncommonly, tall, spiked P waves.

*Cardiac catheterization* shows right ventricular hypertension. The catheter enters the aorta directly from the right ventricle; it may pass across the foramen ovale or an atrial

FIG. 259. Teleroentgenogram in complete transposition of the great vessels (arteries), showing cardiac enlargement and gross pulmonary overvascularity.

septal defect, or across a ventricular septal defect, into the pulmonary artery. The blood in the pulmonary artery has a higher oxygen content than that in the aorta. The shunt is usually bidirectional if there is an associated ventricular septal defect. At the atrial level the shunt is usually from right to left. If the ductus remains patent, the shunt is usually from pulmonary artery to aorta.

*Selective angiocardiography* by injection of contrast material into the right ventricle is diagnostic. It demonstrates the origin of the anteriorly placed aorta from the right ventricle and the presence or absence of an associated ventricular defect or patent ductus.

**Prognosis and Treatment.** The majority of patients succumb during infancy. The occasional child who survives to adolescence usually has an associated pulmonary stenosis and a large ventricular septal defect.

*Treatment* is symptomatic and directed toward relief of congestive cardiac failure, paroxysmal dyspneic attacks and intercurrent pulmonary infections. Surgical treatment has been attempted without much success. These procedures include the following: (1) creation of an atrial septal defect and subclavian to pulmonary anastomosis, (2) redirection of venous blood (i.e., vena caval anastomosis to the left atrium and pulmonary veins to the right atrium), (3) end-to-end anastomosis of the origin of the pulmonary artery to the aorta and the origin of the aorta to the pulmonary artery, (4) insertion of a new atrial septum to direct systemic venous blood to the left ventricle and pulmonary venous blood to the right ventricle.

#### TRANSPOSITION OF THE GREAT VESSELS (ARTERIES) IN ASSOCIATION WITH OTHER DEFECTS

**With Pulmonary Stenosis.** This condition assumes some importance because it may mimic abnormalities which are surgically treatable, e.g., tetralogy of Fallot. The time of onset of symptoms is variable from soon after birth to late infancy and depends largely on whether a ventricular septal defect is present. In such cases oxygenated blood from the left ventricle meets the resistance of the pulmonary stenosis and may result in a shunt of arterialized blood into the aorta. Manifestations include cyanosis, hypercyanotic (paroxysmal dyspneic) episodes, poor physical development and sometimes congestive heart failure. The cardiac findings are similar to those described under Tetralogy of Fallot. However, the cyanosis is usually more in-

tense, and the heart is usually larger. In contradistinction to uncomplicated transposition of the great vessels (arteries), pulmonary undercirculation is usual. During the first few months of life the electrocardiogram may resemble that found in tricuspid atresia. However, in older patients right ventricular hypertrophy, occasionally combined with left ventricular hypertrophy, is common. Selective angiocardiography is of help in making the correct diagnosis.

Patients with transposition and pulmonary stenosis benefit from a Blalock-Taussig or Potts anastomosis, but some arterial unsaturation is usual postoperatively.

**With Tricuspid Atresia.** The clinical picture is similar to that described under Tricuspid Atresia with underdeveloped right ventricle. However, because the pulmonary artery arises from the left ventricle, pulmonary overcirculation is frequent. The prognosis is extremely poor, and these patients usually succumb during infancy.

**With Single Ventricle.** The clinical picture is similar to that described under Transposition of the Great Vessels. In some instances these patients may survive to early childhood or even adolescence. Treatment is entirely symptomatic.

#### TRANSPOSITION OF AORTA AND OVERRIDING PULMONARY ARTERY (TAUSSIG-BING SYNDROME)

In this rare malformation the aorta arises from the right ventricle, and the pulmonary artery, which is large, overrides the ventricular septum. A ventricular septal defect is always present. Cyanosis is usually present from birth. A systolic murmur is usual down the left sternal border and is followed by a loud split second sound. The heart is large, the pulmonary artery prominent and the pulmonary vascularity is increased. The diagnosis is established by selective injection of contrast material into the right ventricle. The prognosis is poor, and the treatment symptomatic.

#### EBSTEIN'S DISEASE

This abnormality consists in the displacement of an abnormal tricuspid valve into the right ventricle. The anterior cusp of the valve retains some attachment to the valve ring, but the other leaflets are attached to the wall of the right ventricle. The latter chamber is divided into two parts by the abnormal valve; the first is continuous with the cavity of the

right atrium, and the second consists of a thin-walled right ventricle. The right atrium is huge, and the tricuspid valve may or may not be competent.

*Symptoms* are frequently mild. Cyanosis is usually absent, but may be present with an associated atrial septal defect. Paroxysmal tachycardia may occur. The venous pressure is normal or, if there is associated tricuspid insufficiency, increased. The heart is usually greatly enlarged, but on palpation the precordium is quiet. A systolic murmur, sometimes accompanied by a thrill, is audible over most of the anterior left chest. Gallop rhythm is common, as is a diastolic murmur down the left sternal border. This murmur is superficial and may mimic a pericardial friction rub.

The *electrocardiogram* shows incomplete or complete right bundle branch block, normal or tall P waves and normal or prolonged P-R interval. *Roentgen examination* shows cardiac enlargement due to right atrial and ventricular dilatation, pulmonary undercirculation and a small aorta. This clinical picture is characteristic and does not require further study for confirmation; *cardiac catheterization* and *angiocardiography* are dangerous in these patients. In the reported cases of successful cardiac catheterization the pressures in the right heart are normal and of small amplitude. Right atrial and ventricular pressures are similar and frequently indicate the presence of tricuspid insufficiency. The arterial oxygen saturation varies and depends on the degree of right-to-left shunt across the foramen ovale; it is frequently between 85 and 90 per cent.

The *prognosis* is extremely variable, and *treatment* is entirely symptomatic.

## TRUNCUS ARTERIOSUS

This condition is due to failure of development of the aortico-pulmonary septum, resulting in persistence of the fetal common arterial trunk. A single large vessel arises from both ventricles and overlies a ventricular septal defect; the valve between the heart and the truncus is quadricuspid or bicuspid. The pulmonary arteries arise from the truncus, usually in its ascending portion.

Much confusion has arisen concerning the anatomy and hemodynamics of truncus arteriosus. The definition given above is that of *true* truncus arteriosus. When a single artery arises from the ventricles and the pul-

monary flow is supplied by enlarged bronchial vessels, this condition is pulmonary atresia and not truncus arteriosus. True truncus arteriosus in which the lungs are supplied by both pulmonary and bronchial arteries is rare.

**Hemodynamics.** Both ventricles empty their blood at systemic pressure into the truncus. In the presence of a normal pulmonary vascular resistance, the blood flow to the lungs is greatly increased, the arterio-venous oxygen difference small and cyanosis is minimal or absent. When the pulmonary resistance is high, the pulmonary circulation is inadequate, and cyanosis is intense.

**Clinical Manifestations.** Owing to the extremely variable hemodynamics, the clinical picture varies. In the presence of a large pulmonary blood flow symptoms may be mild. However, in the majority of patients dyspnea, fatigue, heart failure and poor physical development are frequent. Cyanosis, polycythemia and clubbing may be absent, minimal or intense. If the pulmonary blood flow is large, the pulse pressure is wide with the resultant peripheral signs of a water-hammer pulse. The heart is usually enlarged, and the precordium is hyperdynamic. A systolic ejection murmur, sometimes accompanied by a thrill, is usual down the left sternal border. The second heart sound is loud. Basal diastolic murmurs may be audible. These are due to insufficiency of the valve between the ventricles and the truncus or to collateral bronchial circulation, when the murmur is continuous. In the latter instance the differentiation from pulmonary atresia may be difficult. The electrocardiogram is variable and shows pure right, pure left or combined ventricular hypertrophy. Roentgen examination shows a prominent large vessel which takes the usual course of the aorta (Fig. 260). Cardiac enlargement is due to prominence of both ventricles. The shadow of the main pulmonary artery is absent. The pulmonary vascularity is increased in the presence of a normal pulmonary resistance; it decreases as the resistance rises.

The *diagnosis* is confirmed by cardiac catheterization and by selective angiocardiography with injection of contrast medium into the right ventricle. The catheter may enter the pulmonary arteries from the truncus. A left-to-right shunt is demonstrated at the ventricular level, and the systolic pressures in both ventricles, truncus and pulmonary arteries are similar. Angiocardiography

FIG. 260. Teleroentgenogram in truncus arteriosus. The bizarre supracardiac shadow is produced by the truncus (see text).

reveals the large truncus arteriosus and the origin of the pulmonary arteries from its ascending portion.

The *prognosis* is variable. Although many patients succumb during infancy, some survive to adolescence or even later. *Treatment* is symptomatic.

### SINGLE VENTRICLE

#### (COR TRILOCULARE BIATRIATUM)

Absence of the ventricular septum with normal atria is usually associated with other cardiac anomalies. These consist of one or any combination of the following: (1) transposition of the aorta and pulmonary artery, (2) a rudimentary outflow chamber giving rise to the aorta, pulmonary artery or both, (3) pulmonary stenosis.

The clinical picture is variable. Dyspnea, fatigue, poor physical development, varying degrees of cyanosis and episodes of heart failure are usual. The pulse and blood pressure are normal. The heart is usually enlarged. A loud ejection systolic murmur is audible down the left sternal border and may be followed by a mid or late diastolic murmur.

The electrocardiogram may show left or right ventricular hypertrophy, or the precordial leads across the chest may show a single pattern. Roentgen examination confirms the cardiac enlargement. The rudimentary outflow chamber is sometimes visible on the left cardiac border in the anteroposterior projec-

tion above the ventricular shadow. The pulmonary vascularity may be increased; it is decreased in the presence of pulmonary stenosis.

Cardiac catheterization reveals a left-to-right shunt at the ventricular level. The pressure in the single ventricle is high, and a gradient may be demonstrated between it and the rudimentary outflow tract or the pulmonary artery in the presence of pulmonary stenosis. Selective angiocardiology by injection of contrast medium in the single ventricle shows absence of the ventricular septum and identifies the associated abnormalities.

A large number of these patients succumb during infancy from congestive heart failure and superimposed pulmonary infection. The prognosis appears to be better if there is associated pulmonary stenosis. Treatment is symptomatic.

### AORTIC ATRESIA

Aortic atresia is a severe congenital malformation consisting in underdevelopment of the ascending aorta and its arch, the left ventricle and left atrium. The right ventricle and atrium are enlarged, and the ductus arteriosus is widely patent. It has been suggested that this malformation is produced in some instances by premature closure of the foramen ovale during fetal life.

Venous blood returning to the right atrium passes into the right ventricle and pulmonary artery. The larger part of the venous blood passes through the patent ductus arteriosus to the descending aorta and retrograde to the arch of the aorta. The aortic valve is usually atretic or has a small opening, the mitral valve is small, and the ascending aorta is hypoplastic but patent. Associated endocardial sclerosis of the left ventricle is common.

Signs of heart failure appear within the first few weeks of life and include dyspnea and hepatomegaly. Cyanosis of varying intensity is usual. Differential cyanosis may be striking if the aortic valve has a small opening. In these patients oxygenated blood from the left ventricle enters the ascending aorta and innominate artery, resulting in a normal color in the right arm and right side of the head and neck with a contrasting cyanosis in the rest of the body. Cardiac enlargement is usual. In many cases murmurs are not audible and, if present, are not characteristic. Roentgen studies confirm the cardiac enlargement and show an increase in the pulmonary vascular markings. The electrocardiogram

shows evidence of right ventricular hypertrophy.

The majority of patients succumb during the first month of life. Treatment is symptomatic.

### DEXTROCARDIA WITH SITUS INVERSUS

Dextrocardia indicates that the heart is in the right hemithorax, the apex pointing to the right. This condition is frequently associated with situs inversus with abdominal and thoracic organs transposed to opposite sides of the body. Bronchiectasis and paranasal sinusitis may complicate dextrocardia with situs inversus (Kartagener's syndrome).

In infancy the bedside diagnosis of dextrocardia may be difficult. The apical impulse is in the right side of the chest, and the heart sounds may be louder on the right. Fluoroscopic examination localizes the position of the heart clearly, and with barium the stomach is demonstrated under the right diaphragm. The electrocardiogram is characteristic. Lead I is the mirror image of the normal tracing with inverted P and T waves, and these waves are upright in aVR.

Structural cardiac defects are less frequent than with dextrocardia without situs inversus, and the heart may be functionally normal.

The *prognosis* depends on the presence or absence of associated cardiac defects. Conditions, such as left diaphragmatic hernia or eventration, agenesis or collapse of the right lung, emphysema or cysts of the left lung, left pleural effusion, and the like, which displace the heart into the right chest seldom produce problems in *differential diagnosis*.

### ISOLATED DEXTROCARDIA

In this condition the heart is in the right hemithorax, but the abdominal viscera are in their normal positions. In the majority of instances there are severe cardiac malformations. The commonest ones are tricuspid stenosis or atresia with transposition of the great vessels or single ventricle and transposition of the great vessels (Keith, Rowe and Vlad); tetralogy of Fallot is rare.

The clinical picture is dominated by the dextrocardia and the associated cardiac anomalies. The prognosis is poor; most patients succumb during infancy. However, when there is a pulmonary stenosis, an anastomotic procedure may be beneficial.

### LEVOCARDIA WITH SITUS INVERSUS

The heart is in its normal anatomic position, but the abdominal viscera are totally or partially transposed. In the majority of instances severe cardiac malformations coexist, the commoner ones being (1) a single ventricle with atrioventricular canal, transposition of the great vessels and pulmonary stenosis or atresia, (2) atrioventricular canal with transposition of the great vessels and pulmonary stenosis or atresia, (3) anomalous systemic and pulmonary venous return (Keith, Rowe and Vlad). Splenic abnormalities are common and consist of congenital absence, rudimentary spleen or multiple small spleens.

The clinical picture is generally dominated by the coexisting cardiac malformations. The prognosis is usually poor; the majority of patients succumb during infancy. If the pulmonary blood flow is reduced owing to associated pulmonary stenosis, anastomotic shunts can be advised.

### PULMONARY ARTERIOVENOUS FISTULA

Congenital localized or multiple fistulous communications may occur in the vasculature of the lungs. Such an anomaly produces a shunting of venous blood from the pulmonary artery to the pulmonary veins. Cyanosis, clubbing and polycythemia usually result from the veno-arterial communication.

Exertional dyspnea is often present, and there is a history of recurrent hemoptysis in about 50 per cent of patients. The heart is usually normal in size and contour. Systolic and diastolic bruits are often heard over the

FIG. 261. Teleroentgenogram in pulmonary arteriovenous fistula, showing a localized increase in pulmonary vascularity in the right lung.

FIG. 262. Angiocardiogram in pulmonary arteriovenous fistula. (Same patient as Fig. 261.) The contrast medium has delineated the extent of the fistula in the right lung.

site of a fistulous communication. The pulmonary lesions may be single or multiple and may be associated with widely distributed aneurysms, especially in the skin and in the mucous membranes of the nasopharynx.

Roentgen studies show areas of localized increase in vascular markings, which at times may be confused with chronic pulmonary infection (Fig. 261). On fluoroscopy the

vascular lesions may be seen to pulsate. Angiocardiography demonstrates the location and extent of the lesion (Fig. 262). The electrocardiogram is normal in all respects.

Excision of localized fistulas by lobectomy results in a dramatic disappearance of cyanosis and other symptoms.

### ECTOPIA CORDIS

This is a rare malformation in which the heart is in an abnormal location. In the commonest form, thoracic in type, the sternum is split, and the heart protrudes outside the chest. In others the heart protrudes through the diaphragm into the abdominal cavity, or it may be situated in the neck. Death occurs in the first few days of life in the majority of instances.

### DIVERTICULUM OF THE LEFT VENTRICLE

This is a rare anomaly protruding through a defect in the diaphragm into the epigastrium. A pulsating mass is visible and palpable in the upper part of the abdomen. Such a diverticulum has been successfully excised.

## CONGENITAL HEART DISEASE WITH LITTLE OR NO CYANOSIS (DOMINANT LEFT-TO-RIGHT SHUNT OR NO SHUNT)

### VENTRICULAR SEPTAL DEFECT

Defects in the ventricular septum are among the commonest malformations of the heart. The opening may be situated anywhere in the ventricular septum, and occasionally there is more than one defect. These defects are most frequently situated in the membranous portion of the ventricular septum and may be closely related to the aortic valve and to the septal leaflet of the tricuspid valve.

**Hemodynamics.** In the majority of instances the systolic pressure in the left ventricle exceeds that in the right ventricle. This results in a large pressure gradient, and during left ventricular systole blood is shunted across the defect into the right ventricle. Thus the normal right ventricular output is supplemented by the increment of the shunt across the ventricular defect. Therefore the pulmonary arterial flow is increased, as is the return of pulmonary venous blood to the left atrium and ventricle. The right ventricular and pulmonary artery pressures as well as the pulmonary arteriolar resistance may be nor-

mal or moderately or greatly increased. The factor or factors which determine the presence or absence of pulmonary hypertension are not clear. The amount of left-to-right shunt is not the cause of pulmonary hypertension because in atrial septal defect there may be a huge pulmonary blood flow with normal pulmonary pressures. Other factors to be considered in the etiology of pulmonary hypertension in ventricular septal defect include the size of the defect, the fact that the right ventricle and pulmonary artery are exposed to left ventricular pressures during systole and the persistence of the neonatal high pulmonary arteriolar resistance (see also Eisenmenger Syndrome, p. 849).

**Clinical Manifestations.** These are extremely variable. In some patients there are none; in others heart failure and death may occur at any time, but especially during infancy. The factor which determines the presence or absence of symptoms is the degree of elevation of the pulmonary artery pressure and pulmonary arteriolar resistance.

In the asymptomatic child the lesion is

generally detected during a routine physical examination, and the parents are surprised to learn that the child has congenital heart disease. In other patients the history includes recurrent episodes of pulmonary infection frequently complicated by heart failure during infancy, poor physical development, fatigue and dyspnea on exertion. The history of unusual dyspnea with exercise may be difficult to elicit and may require repeated and careful questioning.

On physical examination the venous pressure is normal unless there is congestive heart failure. The pulse and blood pressure are not unusual. Cyanosis is absent. In asymptomatic patients with normal pulmonary artery pressures the heart is not enlarged and there is no abnormal apical thrust. In others the heart is moderately or greatly enlarged. In the latter group palpation of the precordium reveals a hyperdynamic left ventricular apical thrust, a left sternal border right ventricular lift and pulsations in the second left parasternal space due to an enlarged pulmonary artery. These signs indicate biventricular hypertrophy. In the majority of instances a systolic thrill is palpable maximally at the lower left sternal border, but may radiate widely over most of the precordium. The murmur is loud, pansystolic and maximal down the left sternal border, especially in the third, fourth and fifth interspaces. The second heart sound is split, and the pulmonary element is accentuated, especially in the presence of pulmonary hypertension. A functional, apical, low-pitched mid-diastolic murmur is frequent and is probably due to the large blood flow across the mitral valve. In patients with pulmonary hypertension, a functional pulmonary diastolic murmur (Graham Steell) may be audible.

*Roentgen examination* in the asymptomatic patient with normal pulmonary pressures is usually normal. In the symptomatic group the heart is enlarged, owing to left and right ventricular prominence. The pulmonary artery is enlarged and the intrapulmonary vascularity increased with or without a hilar dance. The aorta may be small, normal or prominent.

The *electrocardiogram* is normal in the asymptomatic patients. In others the tracing shows left and right ventricular hypertrophy with or without incomplete right bundle branch block. Some patients show isolated left or right ventricular hypertrophy. In the majority of instances the graph shows right axis deviation with a vertical heart. However,

in others the axis is left, and the heart is horizontal. In the latter instance, especially if there is associated biventricular hypertrophy and incomplete right bundle branch block, the graph may simulate that seen in ostium primum defect.

*Cardiac catheterization* reveals a left-to-right shunt at the ventricular level due to the entry of arterialized left ventricular blood into the right ventricle. The pressures in the lesser circulation vary from normal to elevated ones approaching systemic levels. In some instances a small gradient of pressure is measured across the outflow of the right ventricle which is probably due to functional hypertrophy of the crista supraventricularis. If the catheter passes across a patent foramen ovale and enters the left ventricle from the left atrium, injection of contrast medium into the left ventricle demonstrates the location of the ventricular defect. The left-to-right shunt is also demonstrable by dye dilution techniques.

**Prognosis and Complications.** Ventricular defect is a serious abnormality. The previously suggested good prognosis of ventricular defect is probably related to the fact that many accidental murmurs and those of slight pulmonary or aortic stenosis were misdiagnosed as ventricular defect. In Selzer's series of 88 fatal cases 29 per cent of patients died during the first year of life, and 20 per cent between the ages of one and five years. The complications of severe pulmonary hypertension with bidirectional or reversed shunt have

FIG. 263. Teleroentgenogram in ventricular septal defect. Note the cardiac enlargement, prominent pulmonary artery segment and pulmonary overcirculation. This radiographic picture may be simulated by atrial septal defect and partial anomalous pulmonary venous return.

been described under the Eisenmenger syndrome. Subacute bacterial endocarditis may complicate ventricular defects in about 10 to 20 per cent of cases (Wood). The vegetations may be found on the defect, the opposite wall of the right ventricle, the wall of the left ventricle or the aortic valve. Owing to the direction of flow across the defect, pulmonary emboli are common. Congestive heart failure may occur at any age, but is most frequent during infancy and is usually precipitated or accompanied by pulmonary infection.

**Treatment.** With the advent of direct-vision, open-heart surgery with the use of a pump oxygenator, ventricular septal defects can be repaired; the left-to-right shunt is obliterated, the hyperdynamic heart becomes quiet, thrills and murmurs are abolished, and the pressures in the lesser circulation are returned to normal. In some instances after successful surgery, systolic ejection murmurs of low intensity persist for some months, owing to turbulence in the pulmonary artery.

The indications for surgery are not clearly defined. The ideal candidate is the symptomatic patient over the age of two years whose systolic pressure in the pulmonary artery is between 50 and 70 mm. of mercury and who has a large left-to-right shunt. In these patients the surgical mortality rate is 5 per cent or less. Patients who have pulmonic systolic pressures at or approaching the systemic level, but without demonstrable right-to-left shunt and large left-to-right shunts, are still good candidates for surgery, but the surgical mortality rate is higher. It appears at present that patients with demonstrable right-to-left shunts and small left-to-right shunts are inoperable (see Eisenmenger Syndrome). Infants with symptomatic ventricular defects present a difficult problem in management, since open-heart surgery has a higher mortality rate during the first year of life. In spite of the apparent high mortality rate with medical management in this age group, it is often possible to revert episodes of heart failure and pulmonary infection with diligent and careful treatment. If these measures fail, surgery can be considered; the risk of delay must be weighed against the operative risk. Before the advent of surgery the authors observed patients who had recurrent episodes of heart failure, pulmonary infection and poor weight gain (e.g., weight of 10 pounds at the age of one year) who survived to be successfully treated with surgery in later years. When patients are asymptomatic, have

a normal-sized heart, normal electrocardiogram and normal pressures in the lesser circulation, it is preferable to defer surgery.

Medical management in the years prior to surgery is important. The therapy in the symptomatic infant has been mentioned. As a protection against subacute bacterial endocarditis, the child should receive large doses of penicillin for forty-eight hours before and seventy-two hours after dental extractions, tonsillectomy and adenoidectomy. Similarly, intercurrent infections should be treated diligently with suitable antibiotics.

#### **VENTRICULAR SEPTAL DEFECT WITH AORTIC INSUFFICIENCY**

In rare instances ventricular septal defect is complicated by prolapse of the aortic valve and aortic insufficiency. The physical signs are those of ventricular septal defect and aortic insufficiency. The diastolic murmur is clearly due to aortic insufficiency, because it is associated with the peripheral signs of a wide pulse pressure. These defects may be confused with patent ductus arteriosus.

#### **VENTRICULAR SEPTAL DEFECT WITH LEFT VENTRICULAR, RIGHT ATRIAL SHUNT**

Ventricular defects may be closely associated with an abnormal septal leaflet of the tricuspid valve. Thus, during left ventricular systole, arterialized blood is ejected through the defect into the right atrium. The physical signs are those of ventricular septal defect or ostium primum defect. In addition, the high right atrial pressure is manifest as a large systolic venous pulsation in the neck. Cardiac catheterization reveals a left-to-right shunt at the atrial level and may result in a misdiagnosis of atrial septal defect. However, the right atrial pressure curve shows a large "c" wave and, in contrast to ostium secundum atrial defects, the right ventricular and pulmonary artery pressures are usually elevated. These patients are treated surgically by closure of the ventricular defect as described above.

#### **OTHER DEFECTS ASSOCIATED WITH VENTRICULAR SEPTAL DEFECT**

With the advent of surgery for ventricular septal defects the correct diagnosis of associated cardiovascular malformations becomes of paramount importance. These associated defects include the following:

**Patent Ductus Arteriosus.** During cardiopulmonary bypass for the repair of ventricular

defects arterialized blood from the heart-lung apparatus is returned to a branch of the aorta. If there is an associated patent ductus arteriosus, there is a leak of blood into the pulmonary artery which results in flooding the surgical field with blood, and may contribute to postoperative pulmonary complications. In some instances the physical signs are dominated by those of the ventricular septal defect, and the murmur of the patent ductus is inaudible. In these patients the diagnosis is established by the passage of the cardiac catheter from the pulmonary artery, through the ductus and into the descending aorta.

In other instances the signs are dominated by those of patent ductus arteriosus, although a systolic murmur and thrill are often present along the lower left sternal border. In these cases cardiac catheterization and selective angiocardiography reveal the left-to-right shunt at the ventricular level as well as the patent ductus arteriosus.

Both the ventricular defect and the patent ductus are treated surgically at the same operation. If the presence of the open ductus is appreciated, the surgical risk is the same as that for uncomplicated ventricular defect.

**Multiple Ventricular Septal Defects.** In rare instances there is more than one ventricular septal defect. Because this cannot be appreciated clinically or by cardiac catheterization, exploration of the whole ventricular septum is indicated during open cardiomy to ensure that all defects have been treated.

**Atrial Septal Defect.** In patients with a ventricular defect and an ostium secundum atrial defect the physical signs are usually dominated by the ventricular defect. This combination of defects may be suspected during cardiac catheterization if a left-to-right shunt is demonstrated at the atrial level and another at the ventricular level. During right ventriculotomy for closure of ventricular defects the atrial septum is easily explored through the tricuspid valve, and, if both defects are present, they can be treated during the same surgical procedure.

**Coarctation of the Aorta.** The signs of coarctation of the aorta are clear, but those of the ventricular defect may be confused with the signs produced by the collateral circulation secondary to the coarctation. It is frequently difficult to treat both abnormalities through the usual incision for cardiopulmonary bypass, and it may be necessary to repair these lesions at separate surgical procedures.

**Persistent Left Superior Vena Cava.** This condition is not diagnosable clinically. It is proved by cardiac catheterization when the catheter enters the persistent left superior vena cava from the coronary sinus. Surgical treatment of ventricular defects with cardiopulmonary bypass requires occlusion of the venous inflow. If the left superior vena cava is not occluded, large volumes of venous blood enter the heart during cardiomy. The persistent left superior vena cava in itself does not require treatment.

**Endocardial Sclerosis.** Thickened white areas are frequently found in the endocardium of the right ventricle in patients with ventricular septal defect. These areas are presumably produced by the jet of blood shunting across the defect to the opposite right ventricular wall. Endocardial sclerosis involving the left atrium and ventricle is not frequently associated with ventricular defect.

**Complete Heart Block.** This arrhythmia is rare in patients with ventricular septal defect, although systolic murmurs of varying intensity are not unusual in patients with complete heart block. They are produced by the turbulence associated with the large stroke volume. If patients with complete heart block are to have a ventricular septal defect corrected, transposition of the great vessels should also be suspected. These abnormalities do not contraindicate surgical closure of the ventricular defect.

## ATRIAL SEPTAL DEFECT

### PATENT FORAMEN OVALE

The foramen ovale is an important structure during intrauterine life allowing the shunting of inferior vena caval blood from the right atrium to the left atrium. At or soon after birth the foramen ovale closes. In about 80 per cent of normal hearts the closure is permanent; in the remainder a small slitlike opening remains patent.

An isolated patent foramen ovale is of no clinical significance. If the right atrial pressure is increased (e.g., secondary to pulmonary stenosis or pulmonary hypertension), venous blood may be shunted across the patent foramen ovale into the left atrium and result in cyanosis. A cardiac catheter introduced from the saphenous vein into the inferior vena cava and right atrium may pass easily across a patent foramen ovale into the left atrium.

Because of the anatomic structure at the

valve of a patent foramen ovale, blood cannot be shunted from the left atrium to the right atrium.

An isolated patent foramen ovale does not require treatment.

### OSTIUM SECUNDUM DEFECT

The ostium secundum type of atrial septal defects are large openings and are associated with normal atrioventricular valves. The anatomic location of these defects depends on the time of arrested development of the septum primum or secundum. They may be situated anywhere in the atrial septum, including the lower anterior part of the septum, the region of the fossa ovalis or posteriorly. Occasionally ostium secundum defects are multiple.

**Hemodynamics.** A considerable shunt of oxygenated blood flows from the left to the right atrium. This blood is added to the normal venous return to the right atrium and is pumped by the right ventricle to the lungs. The large blood flow through the right side of the heart results in enlargement of the right atrium and ventricle and dilatation of the pulmonary artery. In spite of the large pulmonary blood flow, the pulmonary arterial pressure is usually normal or moderately elevated. The left ventricle and aorta are small, owing to the relatively small amount of blood that they carry. Progressive dilatation of the right ventricle leads to heart failure. Cyanosis is extremely rare; it is seen occasionally with congestive heart failure or with the complicating features of the Eisenmenger syndrome.

**Clinical Manifestations.** In many children the condition is asymptomatic and discovered during routine physical examination. Ostium secundum defects rarely produce heart failure in infancy. The history in older children usually includes recurrent episodes of bronchopneumonia frequently complicated by segmental pulmonary collapse, varying degrees of exercise intolerance and poor physical development. In many instances the patients are completely asymptomatic during the first two decades of life.

The pulse is normal or small and the venous pressure normal unless there is associated tricuspid insufficiency or heart failure. The heart may be normal in size or moderately or greatly enlarged. A hyperdynamic right ventricular systolic lift is usually palpable and extends from the left sternal border to the mid-clavicular line. On auscultation a mid-systolic ejection murmur usually of low

intensity, but occasionally accompanied by a thrill, is audible maximally over the pulmonary area and radiates down the left sternal border. The murmur is preceded by a loud first heart sound. The second heart sound is widely split, does not vary with respiration and is due to prolongation of the right ventricular systole (Wood). A mid-diastolic murmur may be audible at the apex and/or at the lower left sternal edge. The diastolic murmur of pulmonary incompetence may be heard, but is rare. Leatham and Gray ascribe the systolic murmur to the large pulmonary flow and the loud first sound and mid-diastolic murmur to the increased tricuspid flow.

Associated abnormalities which may be found on physical examination include pigeon chest, kyphoscoliosis, high arched palate and arachnodactyly. Congenital or rheumatic mitral stenosis with atrial septal defect (*Lutembacher syndrome*) is rare, and its frequency has been overemphasized.

*Roentgen examination* shows varying degrees of cardiac enlargement due to prominence of the right ventricle and atrium. The pulmonary artery is large, the pulmonary vascularity greatly increased, and hilar dance is not unusual. The left ventricle and aorta are small. These signs vary and in the less advanced cases may not be conspicuous.

The *electrocardiogram* is abnormal in nearly all instances, revealing evidence of incomplete right bundle branch block (Fig. 242), of right ventricular hypertrophy or of

FIG. 264. Teleroentgenogram in atrial septal defect (ostium secundum). Note the cardiac enlargement, prominent pulmonary artery segment, pulmonary overcirculation and small aorta.

a combination of both these signs. Occasionally complete right bundle branch block is present.

The diagnosis may be confirmed by *cardiac catheterization*, which demonstrates a significantly higher oxygen content of the blood from the right atrium as compared to samples from the venae cavae. This finding is not diagnostic of atrial septal defect and may be found with anomalous pulmonary venous return to the right atrium, with ventricular septal defect with tricuspid insufficiency and with ventricular septal defects associated with left ventricular right atrial shunts.

*Dye dilution curves* with injection into the pulmonary artery, right side of the heart and venae cavae usually help to distinguish the foregoing abnormalities from atrial septal defect. The catheter frequently enters the left atrium from the right atrium. *Selective angiocardiology* with injection of contrast material into the left atrium demonstrates the shunt at the atrial level. The pressures in the right side of the heart are variable; they are frequently normal or may show moderate right ventricular and pulmonary hypertension. The pulmonary arteriolar resistance is usually normal, but occasionally may be increased. The shunt across the defect is also variable, but is usually considerable (as high as 20 liters per minute per square meter of body surface.)

**Complications and Prognosis.** Atrial septal defects may be associated with partial anomalous pulmonary venous return or pulmonary stenosis. Functional tricuspid incompetence secondary to dilatation of the right ventricle is not infrequent in the presence of congestive heart failure. Subacute bacterial endocarditis is rare; if it occurs, it suggests the presence of associated abnormalities, e.g., pulmonary stenosis. Eisenmenger and Lutembacher syndromes complicating atrial septal defect have been described.

The *prognosis* is extremely variable. Occasionally death occurs in the first few years of life because of uncontrollable pulmonary infections and congestive heart failure. However, in many instances little disability is experienced until the third decade. The major guides to prognosis appear to be the presence or absence of symptoms and of continuing cardiac enlargement.

**Treatment.** Although many forms of surgical therapy have been introduced to close atrial septal defects, direct-vision, open-heart surgery allows accurate closure. This type of surgery may be accomplished by hypothermia

or with the use of a pump oxygenator and cardiopulmonary bypass. We have preferred the latter form of treatment because the defect may be closed leisurely and because associated defects may be treated during the same procedure. The mortality rate from surgery is less than 2 per cent.

#### OSTIUM PRIMUM DEFECT AND COMMON ATRIOVENTRICULAR CANAL

##### (ENDOCARDIAL CUSHION DEFECTS)

These abnormalities have been grouped together because they have a common embryologic relationship and the clinical pattern may be similar.

*Ostium primum defect* is an atrial septal defect, the lower border of which is formed by the mitral and tricuspid valves. In the majority of instances there is a cleft in the anterior mitral valve leaflet with resultant mitral regurgitation.

*Common atrioventricular canal* is a continuous communication consisting of an ostium primum defect in association with a high ventricular septal defect. In addition, the mitral and tricuspid leaflets are abnormal. They may remain undifferentiated, forming a common atrioventricular valve, or may fuse together through the defect with clefts in either the mitral or tricuspid valve or both.

*Transitional varieties* of these defects also occur, which include ostium primum defects with clefts in the anterior mitral and septal tricuspid valve leaflets, but without a ventricular septal defect, and, less commonly, ostium primum defects with normal atrioventricular valves.

**Hemodynamics.** The shunt of blood across the defect is usually from left to right. In contradistinction to ostium secundum defects, the right ventricular and pulmonary artery systolic pressures are frequently elevated, as is the pulmonary arteriolar resistance. Of great importance is the presence of the mitral valve cleft with resultant mitral insufficiency. Elevation of the pulmonary artery pressure to systemic levels results in a bidirectional shunt and cyanosis (Eisenmenger syndrome).

**Clinical Manifestations.** Endocardial cushion defects are more common among children with mongolism than among other children; mongolism is also associated with a variety of other congenital heart defects. Symptoms, which include recurrent episodes of bronchopneumonia with or without segmental atelectasis, effort dyspnea and poor physical development, may appear at any age from infancy to the second decade or later. The

FIG. 265. Electrocardiogram in ostium primum atrial septal defect. Note the prolongation of the P-R interval, left axis deviation, horizontal electrical position and evidence of biventricular hypertrophy.

jugular venous pressure is increased with congestive heart failure, with tricuspid insufficiency and at times with pulmonary hypertension. The heart is usually enlarged to some degree. The apical impulse is manifest by a left ventricular heave and is associated with a right ventricular sternal and parasternal lift. A systolic murmur sometimes accompanied by a thrill is usually audible. At the apex the murmur is pansystolic (regurgitant), owing to the mitral insufficiency. The systolic murmur along the left sternal border is ejection in type and is probably due to the ventricular septal defect or to turbulence produced by the large pulmonary artery flow. Apical mid-diastolic rumbling murmurs are common. The second heart sound is split, but the degree of it varies from wide to narrow.

*Roentgen examination* confirms the cardiac enlargement, which is due to prominence of both right and left ventricles. The pulmonary artery is large; pulmonary vascularity is increased, and hilar dance is not unusual. The aorta is small or normal in size. The *electrocardiogram* is unusual and frequently diagnostic (Fig. 265). The abnormalities consist in prolongation of the P-R interval, left axis deviation and biventricular hypertrophy. Right ventricular hypertrophy is frequently associated with a slurred R wave in  $V_4R$  and  $V_1$ . Sometimes the pattern in the right ventricular surface leads is that of incomplete

right bundle branch block. Left ventricular hypertrophy is indicated by tall R waves in  $V_5$  and  $V_6$  followed by either tall, flat or inverted T waves.

*Cardiac catheterization* demonstrates a left-to-right shunt at the atrial level as indicated by a high oxygen content of the right atrial blood as compared to the caval blood. A further shunt may be shown at the ventricular level, or sometimes the demonstrable shunt is only at the ventricular level. The pulmonary artery and right ventricular systolic pressures are usually elevated. If they reach systemic levels, the shunt is bidirectional as indicated by arterial oxygen unsaturation and by dye dilution curves. The right atrial pressure is increased in the presence of congestive heart failure or tricuspid insufficiency. The catheter passes across the atrial defect with ease. Selective angiocardiology with injection of contrast material into the left atrium and left ventricle also demonstrates the left-to-right shunt.

**Differential Diagnosis.** Endocardial cushion defects may simulate ostium secundum defects as well as ventricular septal defects. In endocardial cushion defects the symptoms frequently appear early, signs of mitral insufficiency and biventricular hypertrophy are common, and the electrocardiographic changes are usually definitive, although the changes of isolated ventricular septal defect may at times closely simulate them.

The *prognosis* is variable and appears to depend on the degree of mitral insufficiency and the elevation of the pulmonary arteriolar resistance. Death from congestive cardiac failure during infancy is not uncommon. However, many patients with ostium primum defects are asymptomatic or have only minor nonprogressive symptoms until they reach the third or fourth decade of life.

**Treatment.** Direct-vision intracardiac surgery with an artificial heart-lung machine and cardiopulmonary bypass is now a feasible form of treatment for endocardial cushion defects. The defect is approached from an incision in the right atrium. The cleft in the mitral valve is visualized through the atrial defect and is repaired by direct suture. If a cleft is present in the tricuspid valve, it is also treated by direct suture. The defects in the atrial and ventricular septa are usually closed by insertion of a prosthesis; they cannot be treated successfully with blind techniques or during hypothermia. The surgical mortality is higher than that for ostium secundum defects, but is not prohibitive.

## PATENT DUCTUS ARTERIOSUS

During fetal life a large percentage of pulmonary arterial blood is shunted through the ductus arteriosus into the aorta; functional closure of the ductus normally occurs soon after birth. However, if the ductus remains patent, aortic blood is shunted into the pulmonary artery. The aortic end of the ductus is opposite and usually distal to the origin of the left subclavian artery, and it enters the pulmonary artery at its bifurcation. Patent ductus arteriosus is peculiar among congenital cardiac defects in that it occurs frequently as an isolated anomaly. It occurs about twice as frequently in females as in males and is one of the commonest congenital cardiovascular anomalies associated with maternal rubella during early pregnancy.

**Hemodynamics.** The blood flow through the ductus is from the aorta to the pulmonary artery as a result of the higher aortic pressure. The degree of shunt depends on the size of the ductus and the pressure gradient between the aorta and the pulmonary artery. In extreme cases one half to two thirds of the left ventricular output may be shunted through the ductus, and the oxygenated blood recirculates through the pulmonary circulation. In the majority of instances the pressures within the pulmonary artery and the right ventricle and right atrium are normal, but the pulmonary artery and right ventricular systolic pressures may be elevated to moderate or even to systemic levels (see Eisenmenger Syndrome). There is a wide pulse pressure. Cassels and Morse have shown that the total blood volume is increased and that it returns to normal limits after surgical closure of the ductus.

**Clinical Manifestations.** There are usually no symptoms; the lesion is often detected during a routine physical examination. However, symptoms may develop at any age and include slowly progressive exertional dyspnea, followed by left ventricular failure or frank congestive cardiac failure. Retardation of physical growth may be the main complaint. Other, rarer symptoms include precordial pain, probably due to complicating neurocirculatory asthenia, and hoarseness from involvement of the adjacent recurrent laryngeal nerve.

The paucity of symptoms contrasts with the striking physical signs. Dynamically, a patent ductus arteriosus is an arteriovenous shunt of considerable extent; and signs of a large pulse pressure are produced, including

water-hammer radial pulsations and conspicuous arterial Corrigan pulsations in the neck. The low diastolic blood pressure may fall further after exertion. The heart is usually normal in size, but may be moderately or grossly enlarged. The apical impulse is normal or left ventricular and, with cardiac enlargement, is heaving. A thrill, situated maximally in the second left interspace, is present in many instances and may radiate toward the left clavicle and somewhat down the left sternal border or toward the apex. The thrill is usually systolic in time, often extends into diastole and, in some instances, may be palpated throughout the cardiac cycle. The classic murmur has been variously described as machinery, humming top, millwheel or rolling thunder in quality. The murmur begins soon after the onset of the first sound, reaches a maximum intensity at the end of systole and wanes in late diastole. It may be localized to the second left intercostal space or radiate down the left sternal border or to the left clavicle. The murmur is harsh and does not have the blowing quality commonly found in acquired lesions. A few patients have atypical murmurs, especially if there is a large ductus or pulmonary hypertension. If there is pulmonary diastolic hypertension associated with the usual low systemic diastolic pressure, there may be a small or negligible flow across the ductus during diastole. Under these conditions only a systolic murmur is present. Rarely the murmur is confined to diastole; this is probably due to pulmonary valve insufficiency. In patients with a large left-to-right shunt a low-pitched mitral diastolic murmur may be audible and is probably due to the large blood flow across the mitral valve.

The *electrocardiogram* is normal in the majority of instances. If the ductus is large, left ventricular hypertrophy may be present. The diagnosis of uncomplicated patent ductus arteriosus is untenable in the presence of electrocardiographic evidence of right ventricular hypertrophy.

*Roentgenographic studies* commonly reveal evidence of a prominent and vigorously pulsating pulmonary artery. The intrapulmonary vascular markings are increased and sometimes exhibit an intrinsic pulsation or hilar dance. The cardiac size depends on the degree of left-to-right shunt; it may be normal, moderately or grossly enlarged (Fig. 266). The chambers involved are the left atrium and ventricle. The aortic knob is normal or prominent and pulsates vigorously. Rarely,

FIG. 266. Teleroentgenograms in patent ductus arteriosus. *A*, Preoperative. Note the cardiac enlargement, prominent pulmonary artery segment and pulmonary overvascularity. *B*, One year postoperative. The heart size and pulmonary vascularity have decreased. Some prominence of the pulmonary artery segment persists.

calcification may be demonstrated in the wall of the ductus.

The clinical pattern is sufficiently distinctive to allow an accurate diagnosis in the majority of patients. However, in patients with atypical murmurs further confirmatory studies are indicated.

*Cardiac catheterization* reveals a normal or increased pressure in the right ventricle and pulmonary artery. Continuous pressure recordings taken as the catheter is withdrawn from a branch of the pulmonary artery to the main pulmonary artery may show an increase in pressure as the catheter tip passes through the jet of blood shunted from the aorta. Oxygenation of the blood in the pulmonary artery confirms the diagnosis of a left-to-right shunt, but does not exclude an aorticopulmonary septal defect. Samples of blood from the venae cavae, right atrium and right ventricle have a comparable oxygen content. With pulmonary insufficiency some oxygenation of the right ventricular blood may be present. The catheter may pass through the ductus into the descending aorta (Fig. 247, *G*). Angiocardiographic studies may also be of value. Injection of contrast material into the ductus demonstrates the anatomy and the left-to-right shunt. Injection into the outflow tract of the right ventricle may show a washing away of the dye in the pulmonary artery by the shunt of blood from the aorta. Retrograde aortography by injection of contrast medium into the brachial artery shows opacification of the pulmonary artery from the aorta. A localized dilatation of the descending aorta just below the isthmus

may be visualized, possibly produced by the aortic end of the ductus or by a traction aneurysm of the aorta.

**Patent Ductus Arteriosus in Infancy.** An uncomplicated patent ductus arteriosus may on occasion produce symptoms of left-sided heart failure or severe congestive failure during the first two years of life. These symptoms are frequently precipitated by respiratory infections to which these patients are prone. They may also exhibit the other symptoms described above.

It has been said that the typical machinery murmur of patent ductus arteriosus generally appears between the ages of three and five years and that before this time only a systolic murmur over the pulmonary area is audible. As in older children, the presence or absence of the diastolic component of the murmur depends on the pressure relationship between the aorta and the pulmonary artery. If secondary pulmonary hypertension has developed, there is little or no flow of blood during diastole, and only a systolic murmur is present. However, if the pulmonary artery pressure is normal or only moderately elevated, the typical machinery murmur is present early, even in infants a few weeks of age. In addition, the pulse pressure is wide, and the heart is moderately to grossly enlarged, the main chambers involved being the left ventricle and atrium.

*Roentgen examination* confirms the enlargement of the chambers and also reveals prominent pulmonary arteries and increased pulsations in the aorta. The *electrocardiogram* may be normal or may show evidence of left

ventricular dominance or biventricular hypertrophy.

This clinical pattern is sufficiently well recognized so that a diagnosis of uncomplicated patent ductus arteriosus can be made at any age. In atypical cases the diagnosis may be confirmed by the methods described above.

The diagnosis of symptomatic uncomplicated patent ductus arteriosus in infancy is important because surgical treatment of the lesion produces dramatic relief of symptoms and normal cardiovascular dynamics. Surgical therapy is indicated in all symptomatic patients irrespective of age and has been successfully performed in infants as young as two months of age.

**Differential Diagnosis of Patent Ductus Arteriosus.** The diagnosis of uncomplicated patent ductus arteriosus is usually not difficult. However, there are other conditions which produce systolic and diastolic murmurs in the pulmonary area which may be misinterpreted. The characteristics of a *venous hum* have been described elsewhere. *Aortico-pulmonary septal defect* may be clinically indistinguishable from a patent ductus. Similarly, difficulty in diagnosis may occur in patients with a *ruptured sinus of Valsalva into the right side of the heart or pulmonary artery* and in patients with *coronary arteriovenous fistulas*. In these three conditions the dynamics are those of an arteriovenous fistula with a machinery type of murmur and a wide pulse pressure. Sometimes the murmur is not maximal in the pulmonary area, but is heard along the lower left sternal border. Pulmonary arteriovenous fistulas may give rise to a machinery type of murmur (see p. 855).

*Ventricular septal defect with aortic insufficiency and combined rheumatic aortic and mitral insufficiency* may be confused with patent ductus arteriosus because the combination of murmurs produced by these lesions superficially resembles those of patent ductus arteriosus. Careful auscultation and the absence of pulmonary overcirculation usually resolves the diagnostic problem.

**Prognosis and Complications.** Because many patients with patent ductus arteriosus are asymptomatic, the impression may be gained that this lesion is benign. Keys and Shapiro estimated that a patent ductus was responsible for an average reduction of life expectancy of about twenty-three years in men and twenty-eight in women. There are occasional instances of patients living a nor-

mal span with little or no cardiac embarrassment. However, children and young adults who have this anomaly are subject to complications (see below), the frequency of which is great enough to make it clear that the lesion is not an innocuous one. Spontaneous closure of the ductus after infancy is extremely rare.

It has been mentioned that infants may succumb to congestive cardiac failure. This complication, which is not infrequently preceded by attacks of left ventricular failure, may occur at any age, but is most common in the third decade of life. Cardiac failure is treated along the usual medical lines, but it is an urgent indication for operation when the patient's condition permits.

Subacute bacterial endarteritis, the most frequent complication in late childhood or early adult life, may occur at any age. Pulmonary emboli are common, and, when the ductus is involved, systemic emboli may occur. This complication should be vigorously treated with suitable antibiotics and surgical closure of the ductus. The mortality and morbidity rates are much lower if the blood stream can be sterilized before operation. The optimum time for surgical treatment is about three months after cure of the infective process.

Rarer complications include aneurysmal dilatation of the pulmonary artery and/or the ductus, noninfective thrombosis of the ductus with embolization, paradoxical emboli and acquired rheumatic heart disease. Patent ductus arteriosus with pulmonary hypertension (Eisenmenger syndrome) has been described (p. 849).

**Treatment.** Irrespective of the age group, patients with manifestations of a patent ductus arteriosus will derive great benefit from surgical closure of the abnormal shunt (see above). If congestive cardiac failure should develop, surgical treatment should not be postponed for too long a time after adequate digitalis, diuretic and low salt diet therapy, even if some signs of failure persist.

Because the mortality rate of surgical treatment is less than 1 per cent, and the risk otherwise is greater, ligation or division of the ductus is indicated in the asymptomatic patient, preferably between the ages of three and ten years. Surgical therapy in this age group is performed with relative facility, whereas in older persons the regional vessels are more rigid or associated with degenerative changes, and the cardiac reserve is reduced

(Gross). The upper age limit for surgical repair in the asymptomatic patient is about thirty-five years. However, if important symptoms develop at any age, there should be no hesitation to operate. Pulmonary hypertension is not a contraindication to operation if it can be demonstrated that the shunt is from aorta to pulmonary artery and not reversed.

Surgical closure is either by ligation or by division and suture of the ductus; the choice is an individual one.

After closure, symptoms of frank or incipient cardiac failure rapidly disappear. If the patient was physically stunted, there is usually an improvement in physical development within a year or two. The pulse and blood pressure return to normal, and the machinery murmur is replaced by two normal heart sounds. In a small number of patients a grade 1 systolic murmur over the pulmonary area may persist; the murmur may be due to turbulence in a persistently dilated pulmonary artery or rarely to an unsuspected associated ventricular or atrial septal defect. The roentgenographic signs of cardiac enlargement and pulmonary overcirculation also disappear (Fig. 266), and the electrocardiogram becomes normal. If pulmonary hypertension was associated with a left-to-right shunt, the pressure returns to normal.

### AORTICOPULMONARY SEPTAL DEFECT

This communication between the aorta and main pulmonary artery close to their origins is indistinguishable clinically and rarely by technical means from patent ductus arteriosus. Occasionally the murmur is heard maximally in the third and fourth left parasternal spaces, but this is not the rule. If the condition is suspected, the course of the catheter during cardiac catheterization may give the correct diagnosis. In patent ductus arteriosus the catheter enters the pulmonary artery and passes across the ductus into the descending aorta. In aorticopulmonary septal defect the catheter enters the ascending aorta from the pulmonary artery. In many instances the diagnosis is made at thoracotomy undertaken for the erroneous diagnosis of patent ductus arteriosus.

Aorticopulmonary defects can be cured by surgical treatment. In the majority of instances the defect is in the intracardiac portion of the aorta, and cardiopulmonary bypass with a heart-lung machine is necessary for the surgical repair.

### FISTULA OF A CORONARY ARTERY

A congenital fistula may exist between a coronary artery and vein, or a coronary artery may empty directly into the right ventricle. In both instances the signs are similar to those of patent ductus arteriosus, but the machinery murmur may be more diffuse. In patients with *coronary arteriovenous fistula* arterialized blood enters the coronary veins, which in turn empty into the coronary sinus. In such cases the right atrial blood has a higher oxygen content than samples from the cavae. When a *coronary artery empties directly into the right ventricle*, there is a left-to-right shunt at the ventricular level. Treatment consists in surgical abolition of the fistula.

### RUPTURED SINUS OF VALSALVA

One of the sinuses of Valsalva of the aorta may be weakened by congenital or acquired disease and result in aneurysmal formation and rupture, usually into the right atrium or ventricle. The clinical manifestations are similar to those of patent ductus arteriosus, except that the machinery type of murmur may be in an unusual site. Cardiac catheterization demonstrates the level of the left-to-right shunt at the atrial or ventricular level. Retrograde aortography with injection of contrast medium into the ascending aorta demonstrates the site of aneurysm and rupture. Surgical obliteration of the shunt with the use of a heart-lung machine is now feasible.

### PULMONARY STENOSIS (WITH NORMAL AORTIC ROOT)

Although the clinical manifestations of this abnormality were described only recently, it probably comprises about 10 per cent of all congenital heart diseases. Pulmonary stenosis may exist as an isolated abnormality or with defects in the atrial or ventricular septa. However, in all instances the origin of the aorta is normal. This distinction aids in separating the malformation under discussion from tetralogy of Fallot, in which the aorta is dextroposed. However, experience gained from direct-vision open-heart surgery indicates that in many instances dextroposition of the aorta (even in tetralogy of Fallot) may be more apparent than real.

The following is a modification of the

classification of pulmonary stenosis with normal aortic root as suggested by Abrahams and Wood:

1. Simple pulmonary stenosis
  - a. Valvular
  - b. Infundibular
  - c. Combined valvular and infundibular
2. Pulmonary stenosis (valvular or infundibular or both) with arteriovenous shunt
  - a. Pulmonary stenosis with atrial septal defect
  - b. Pulmonary stenosis with ventricular septal defect (acyanotic Fallot)
  - c. Pulmonary stenosis with patent ductus arteriosus
3. Pulmonary stenosis (valvular or infundibular or both) with veno-arterial shunt
  - a. Pulmonary stenosis with ventricular septal defect (hemodynamically similar to tetralogy of Fallot)
  - b. Pulmonary stenosis with reversed interatrial shunt (through patent foramen ovale or atrial septal defect)

#### SIMPLE VALVULAR PULMONARY STENOSIS

In this, the commonest type of isolated pulmonary stenosis, the valve cusps exist as a dome-shaped membrane of varying thickness with a small central or eccentric opening. The ventricular and atrial septa are intact.

**Hemodynamics.** The obstruction to the passage of blood from the right ventricle to the pulmonary artery results in increased systolic pressure and hypertrophy of the right ventricle. The degree of these changes depends on the degree of the pulmonary stenosis. In severe cases the right ventricular pressure may be much higher than the systemic systolic pressure. The pulmonary artery pressure is low or normal. The arterial oxygen saturation is normal, and in severe cases the cardiac output is low and fixed.

**Clinical Manifestations.** Symptoms vary with the degree of stenosis. With mild or moderate pulmonary stenosis there are usually no symptoms. If the stenosis is severe, there is usually some degree of effort dyspnea, and the exercise tolerance may be reduced to walking a few yards. Squatting may occur, but is not as common as with tetralogy of Fallot. Substernal pain and effort syncope are rare manifestations in severe cases.

The physique is frequently normal, and many patients are robust. The facies of patients with a severe type of pulmonary stenosis have been described as being round, bloated or moon-shaped.

With stenosis of a mild degree the venous pressure and pulse are normal. The heart is not enlarged; the apical impulse is normal,

and the right ventricle is not palpable. A loud ejection pulmonary systolic murmur, frequently accompanied by a thrill, is audible maximally over the pulmonary area. The second heart sound may be widely split with a delayed pulmonary element of normal intensity. The electrocardiogram is normal or reveals incomplete right bundle branch block. The only abnormality on roentgen examination is poststenotic dilatation of the pulmonary artery. The heart size, the right ventricle and the pulmonary vascularity are within normal limits.

In stenosis of a moderate degree the physical signs are those described above with variable degrees of exaggeration. The venous pressure may be slightly elevated with an intrinsic "a" wave. A right ventricular sternal lift may be palpable. The electrocardiogram reveals varying degrees of right ventricular hypertrophy (systolic overload), sometimes with a prominent spiked P wave. Roentgen examination reveals the heart to be normal in size or mildly enlarged, owing to prominence of the right ventricle, and the intrapulmonary vascularity may be decreased.

In *stenosis of a severe degree* peripheral cyanosis is sometimes present, owing to a small cardiac output, to compensatory vasoconstriction and to sluggish blood flow through the skin. The arterial oxygen saturation is normal. The venous pressure is usually elevated, owing to a large presystolic jugular "a" wave, which is sometimes transmitted to the liver as a presystolic pulsation. Occasionally a large jugular "c" wave is evident and is due to functional tricuspid incompetence. The heart is moderately or greatly enlarged with a conspicuous sternal and parasternal right ventricular lift which frequently extends to the mid-clavicular line. A loud ejection systolic murmur, frequently accompanied by a thrill, is audible maximally in the pulmonary area and may radiate widely over the whole precordium, into the neck and to the back. The systolic murmur extends into the second sound, making its evaluation difficult. The pulmonary element of the second sound is either inaudible or very late and soft. A right atrial presystolic gallop is usually heard in the presence of a large venous "a" wave (Wood). The electrocardiogram shows gross right ventricular hypertrophy frequently accompanied by a tall spiked P wave (P pulmonale). Roentgen studies confirm the moderate or gross cardiac enlargement with prominence of the right ventricle and atrium.

FIG. 267. Teleroentgenogram in valvular pulmonic stenosis with normal aortic root. The heart size is within normal limits, but there is post-stenotic pulmonary artery dilatation and pulmonary undervascularity.

The pulmonary artery segment is prominent, owing to poststenotic dilatation. The intrapulmonary vascularity is decreased.

Cardiac catheterization demonstrates an abrupt gradient of pressure across the pulmonary valve, the magnitude of which depends on the severity of obstruction. The pulmonary artery pressure is normal or low. The right ventricular systolic pressure is about 30 to 50 mm. of mercury in mild cases, about 50 to 100 mm. in moderate cases, and in severe cases is frequently higher than the systemic systolic pressure. In severe and in some moderate cases the right atrial pressure shows a prominent, frequently giant "a" wave. *Selective angiocardiology* with injection of contrast medium into the right ventricle clearly demonstrates the obstruction. The flow of contrast medium through the stenotic valve in ventricular systole produces a jet of dye which fills the dilated pulmonary artery. The abnormal pulmonary valve is frequently visualized.

**Complications.** Congestive cardiac failure, the most common complication, occurs only in severe cases and may occur at any age, even during the first month of life. The development of cyanosis from a right-to-left shunt across a foramen ovale is described elsewhere. Subacute bacterial endocarditis is not common.

**Course and Prognosis.** Children with mild stenosis can lead a normal life without specific treatment, as may many with moderate

FIG. 268. Pressure curve obtained during cardiac catheterization in a patient with isolated pulmonary valvular stenosis. The lower tracing is the electrocardiogram. The upper curve is the pressure record as the catheter was withdrawn from the pulmonary artery to the right ventricle. Note the abrupt pressure gradient between the right ventricle and pulmonary artery. Compare with Figure 253.

stenosis, although their progress should be evaluated at regular intervals. With severe stenosis the course is rapidly downhill with the development of congestive cardiac failure.

**Treatment.** As indicated above, mild cases and many of moderate severity do not require specific treatment, and such patients should be encouraged to lead normal lives. Dental, ear, nose and throat surgery must be covered with prophylactic penicillin as described elsewhere.

All patients with severe isolated pulmonary stenosis require surgical therapy (*pulmonary valvotomy*). The valve can be cut and dilated blindly through a transventricular approach (Brock procedure); it can be approached through the pulmonary artery with inflow and outflow occlusion of the heart during hypothermia (Swan), or the valvotomy can be performed with the use of an artificial heart-lung machine (the authors' preference). Associated defects such as infundibular stenosis, atrial or ventricular defects which may be unrecognized preoperatively can be repaired at the same time.

Good results should be obtained in the majority of instances. The gradient across the pulmonary valve is reduced or abolished. A pulmonary diastolic murmur due to a surgically created pulmonary valve incompetence is not unusual, but appears to have little clinical significance.

**INFUNDIBULAR STENOSIS**

This condition is due to failure of involution of the bulbus cordis, resulting in a muscular or fibrous obstruction in the outflow tract of the right ventricle. The site of obstruction may be close to the pulmonary valve or well below it; an infundibular chamber is present between the right ventricular cavity and the pulmonary valve. The pulmonary valve is also often abnormal (*combined valvular and infundibular stenosis*).

The *hemodynamics* and *clinical manifestations* are similar to those described under Valvular Pulmonary Stenosis with the following exceptions: (1) The systolic thrill and murmur are frequently maximal in the third and fourth left parasternal spaces, but radiate widely. (2) Poststenotic dilatation of the pulmonary artery may be present, but is not usual. (3) With an infundibular chamber and valvular pulmonary stenosis two pressure gradients may be noted during cardiac catheterization: between the right ventricle and the infundibular chamber and between it and the pulmonary artery. (4) Selective angiography can be diagnostic in the majority of instances. When contrast material is injected into the right ventricle, the site of the infundibular stenosis is demonstrated, the presence of an infundibular chamber is visualized, and associated abnormalities of the pulmonary valve are shown.

The *complications*, *course* and *prognosis*

are similar to those described under valvular pulmonary stenosis.

In severe cases surgical *treatment* is indicated. This is accomplished with the use of an artificial heart-lung machine. The infundibular stenosis is excised under direct vision and a pulmonary valvuloplasty performed, if there is associated pulmonary stenosis. In patients who have a small pulmonary valve ring, attempts are being made to enlarge the outflow of the right ventricle by the insertion of a plastic prosthesis. After surgery the pressure gradients are reduced or abolished.

**PULMONARY STENOSIS WITH ARTERIOVENOUS SHUNT**

Valvular or infundibular pulmonary stenosis or both may be associated with a left-to-right shunt across an atrial septal defect, a ventricular septal defect or a patent ductus arteriosus. The clinical features depend on the degree of stenosis and the magnitude of the left-to-right shunt.

**Pulmonary Stenosis and Atrial Septal Defect.** In patients with dominant valvular pulmonary stenosis and a small left-to-right shunt across an atrial septal defect the clinical picture is indistinguishable from that described under Valvular Pulmonary Stenosis. If the shunt across the atrial defect is large and the pulmonary stenosis slight, the clinical manifestations are similar to those described under Atrial Septal Defect, but the systolic murmur

FIG. 269. Selective cine-angiogram in a patient with isolated valvular pulmonary stenosis. Film speed is 60 frames per second. The tip of the catheter is in the outflow of the right ventricle. The patient is in a slight left posterior oblique projection. The contrast material enters the outflow of the right ventricle and shows the pulmonary valve in diastole. During the next ventricular systole a jet of contrast material passes through the valve and mushrooms into a dilated pulmonary artery.

is harsh and frequently accompanied by a thrill. The diagnosis can be made during cardiac catheterization when a left-to-right shunt is demonstrated at the atrial level, and the pulmonary stenosis is shown by the presence of a pressure gradient across the valve. Selective angiocardiology also shows the presence of pulmonary stenosis, and dye dilution curves confirm the left-to-right shunt across the atrial defect.

**Pulmonary Stenosis and Ventricular Septal Defect.** When the ventricular septal defect is dominant and the pulmonary stenosis is slight, the clinical picture is that of ventricular septal defect, and the presence of pulmonary stenosis is not recognizable. However, during cardiac catheterization a gradient is measured across the pulmonary valve, and the left-to-right shunt is demonstrated at the ventricular level. The recognition of a small ventricular septal defect with dominant valvular or infundibular pulmonary stenosis is also difficult. Even during cardiac catheterization the small shunt across the ventricular defect may not be demonstrated, and the diagnosis of isolated pulmonary stenosis made erroneously.

**Pulmonary Stenosis and Patent Ductus Arteriosus.** In addition to the signs of pulmonary stenosis, a machinery type of murmur is audible over the pulmonary area. This combination of anomalies is suspected in patients with the signs of patent ductus arteriosus and right ventricular hypertrophy. Pulmonary atresia is excluded by the absence of cyanosis and the poststenotic dilatation of the pulmonary artery.

**Treatment of Pulmonary Stenosis with Arteriovenous Shunt.** This group of anomalies is treated by direct-vision surgery during cardiopulmonary bypass with an artificial heart-lung machine. The defects in the atrial or ventricular septa are closed and the pulmonary stenosis treated by infundibular resection or pulmonary valvuloplasty. If the ductus is patent, it is divided during the same procedure. Surgery is recommended only in the severe or progressive cases. After successful surgery the left-to-right shunt is obliterated, and the gradient across the valve is reduced or abolished.

#### PULMONARY STENOSIS WITH VENO-ARTERIAL SHUNT

**With Atrial Septal Defect or Patent Foramen Ovale (Trilogy of Fallot).** As indicated above, patients with moderate or severe

valvular or infundibular stenosis have right ventricular systolic hypertension. If, in addition, the right atrium has difficulty in emptying during right ventricular diastole (which occurs during right atrial systole), the right atrial pressure rises. This results in reversal of the shunt to a right-to-left one across the atrial septal defect and in cyanosis. A similar sequence of events occurs if the foramen ovale is patent.

Cyanosis may be present at birth or appear later, frequently during adolescence, and is accompanied by clubbing and polycythemia. The jugular venous pressure is increased in many instances with an intrinsic "a" wave. Other physical signs and technical data are similar to those described under severe valvular pulmonic stenosis. The right-to-left shunt produces arterial oxygen unsaturation.

Surgical therapy is required in all cases and preferably consists in pulmonary valvotomy and closure of the atrial septal defect with an artificial heart-lung machine.

**With Ventricular Septal Defect.** This condition is similar to that of tetralogy of Fallot (see p. 842).

#### COARCTATION OF THE AORTA

Constrictions of varying length may occur at any point between the arch and the bifurcation of the aorta, but 98 per cent of them occur as a localized stricture just below the origin of the left subclavian artery and about twice as often in males as in females.

**Hemodynamics.** Owing to the mechanical obstruction of the aorta, extensive collateral circulation usually develops, chiefly from the branches of the subclavian artery: the superior intercostal artery and the internal mammary with its intercostal, superior epigastric and musculophrenic branches. The thoracic and subscapular branches of the axillary artery may also enlarge as collateral channels. These vessels unite with the intercostal branches of the descending aorta and inferior epigastric branches of the femoral artery, thus creating a channel for arterial blood to bypass the area of coarctation. The vessels contributing to the collateral circulation become enormously enlarged and tortuous.

The blood pressure is elevated in the vessels arising proximal to the coarctation; below it the amplitude of pulsation is diminished, and the pressure below the constriction is lower than that above it. The basis for the

hypertension is not clear. It does not appear to be due to the mechanical obstruction alone, nor does renal ischemia play a major role.

**Clinical Manifestations.** Although incapacitating symptoms are not usual during the first decade of life, they may develop at any age and are the result of the hypertensive state, myocardial weakness and/or a deficient circulation in the lower extremities. Hypertension may result in epistaxes and throbbing headaches, and the symptoms of left ventricular or frank congestive cardiac failure may occur secondary to the hypertensive state. Cerebral hemorrhages are not uncommon. Deficient circulation to the lower extremities may be evidenced by cold feet and occasionally by intermittent claudication.

The classic sign of coarctation of the aorta is the disparity in pulsations and blood pressures between the upper and lower extremities. The femoral, popliteal, posterior tibial and dorsalis pedis pulsations are weak and delayed or absent, in contrast with the bounding pulses of the upper extremities and carotid vessels. In normal persons the systolic blood pressure in the legs as obtained by the cuff method is about 20 to 40 mm. of mercury higher than that in the arms. In coarctation of the aorta the blood pressure in the legs is much lower than that obtained in the arms; frequently it cannot be obtained. Elevation of blood pressure in the upper extremities may appear at any age from infancy, but hypertension of some degree is the rule in older patients. There is also a rise of blood pressure in response to exercise. It is essential to determine the blood pressure in both upper extremities; a difference of more than 30 mm. between the right and left arms suggests involvement of the left subclavian artery in the area of coarctation.

The collateral arterial circulation may give rise to visible and palpable pulsations and to systolic murmurs, especially in the back between the scapulae and at their angles. These signs are usually more striking after the first decade of life, as is enlargement of the heart with a left ventricular apical impulse. Murmurs are variable in location, intensity and quality and are not diagnostic. The common murmur is systolic in time, maximal over the base of the heart and radiates down the sternum to the apex and to the interscapular area; sometimes it is loudest in the back. The murmur may be produced by the coarctation, by tortuous collateral vessels, by abnormalities of the aortic valve or by associated structural anomalies of the heart such as septal

defects. Occasionally there is also a diastolic element, which may be due to associated congenital or rheumatic aortic insufficiency; it is heard best over the base of the heart and down the left sternal border. A continuous murmur over the pulmonary area radiating to the left clavicle suggests an associated patent ductus arteriosus. Rarely a diastolic murmur is heard in the back, presumably owing to collateral circulation. A rumbling apical diastolic murmur of uncertain origin may also be present; at times it may be due to coincident rheumatic mitral stenosis.

The findings on *roentgen examination* depend on the age of the patient and on the effects of hypertension and collateral circulation. In infancy there are usually no changes except cardiac enlargement if congestive cardiac failure develops. During childhood the findings are not striking except on occasion when the left ventricle is prominent. After the first decade the heart tends to be mildly or moderately enlarged, owing to left ventricular prominence. The enlarged left subclavian artery commonly produces a prominent shadow in the left superior mediastinum. Notching of the inferior border of the ribs due to pressure erosion from enlarged collateral vessels is common by late childhood, except in the upper or lower two or three ribs. Rarely erosion is unilateral and is due to one of the subclavian arteries arising below the area of coarctation. In the majority of instances there is an area of poststenotic dilatation of the descending aorta. This may be manifest by displacement of the barium-filled esophagus and by discontinuity of the lateral margin of the aorta below the arch (Fig. 270). Prominent serrations on the posterior aspect of the barium-filled esophagus suggest the presence of large intercostal arteries entering the aorta below the coarctation. Occasionally scalloping in the soft tissues may be visualized retrosternally; it is due to dilated internal mammary arteries.

The *electrocardiogram* is commonly normal in children, but may reveal evidences of left ventricular hypertrophy and occasionally of left bundle branch block. Other coexisting cardiovascular anomalies should be suspected if right ventricular hypertrophy is present. The pattern of incomplete right bundle branch block may be present in the absence of associated anomalies. The *ballistocardiogram* is usually abnormal, showing a shortened J-K stroke due to a small or absent K wave.

Most often the diagnosis can be made by

FIG. 270. Teleroentgenogram in a 6-year-old boy with coarctation of the aorta. The left ventricle is prominent, but there is no evidence of rib notching. The barium-filled esophagus is indented by the poststenotic dilatation. (Compare with retrograde aortogram, Fig. 271.)

physical examination. Routine examination of all hypertensive subjects and of all infants in whom cardiovascular defects are suspected should include palpation of all the major accessible peripheral arteries. This simple maneuver will make the correct diagnosis obvious. The segment of coarctation can be demonstrated by retrograde aortography or angiocardiology (Fig. 271), but these studies are seldom indicated except when the site of coarctation is considered to be unusual.

**Associated Abnormalities.** Associated defects are not uncommon and may produce gross physical signs which allow a correct diagnosis. Bicuspid aortic valves are relatively common, but usually do not produce any signs unless aortic incompetence or stenosis develops. Rheumatic mitral stenosis and aortic insufficiency are rare complications. The association of patent ductus arteriosus and coarctation of the aorta is discussed later. Ventricular and atrial septal defects may be suspected by the additional signs of left-to-right shunt.

Severe neurologic damage or even death may occur from associated cerebral vascular disease. Subarachnoid or intracerebral hemorrhage may result from rupture of congenital aneurysms in the circle of Willis, of other vessels with defective elastic and medial tissue or of normal vessels; these accidents are secondary to the hypertensive state. Abnormalities of the subclavian arteries may also occur and include involvement of the left subclavian artery in the area of coarctation,

stenosis of the orifice of the left subclavian artery and anomalous origin of the right subclavian artery.

**Prognosis and Complications.** Although some patients with coarctation of the aorta live well into middle life without serious handicap, this is not the usual course. The majority succumb between the ages of twenty and forty years. Symptoms may appear in infancy and are nearly always present by the age of twenty-five years. The common serious complications are those related to the hypertensive state which may result in congestive cardiac failure or intracranial hemorrhage. If heart failure develops, the coarctation is frequently complicated by other anomalies, e.g., bicuspid aortic valve with aortic stenosis and/or insufficiency. Subacute bacterial endocarditis or endarteritis is also a frequent complication and most commonly involves abnormal aortic valves. Rupture of the aorta is also common and is due to defective elastic and medial tissue. Aneurysms of the descending aorta or of the enlarged collateral vessels are not unusual. The natural course in the individual case is unpredictable.

**Treatment.** In view of the natural course of coarctation of the aorta, most patients should be treated surgically. The optimum age for surgery is between eight and fifteen years, because at this time the aorta has a good elasticity with little or no degenerative changes, and the lumen after anastomosis is adequate to carry the patient through adult life (Gross). The mortality rate at this age is less than 2 per cent. After the second decade the operation is more hazardous, owing to a decreased cardiac reserve and de-

FIG. 271. Retrograde aortogram in coarctation of the aorta. (Same patient as Fig. 270.) The areas of coarctation and poststenotic dilatation are visualized.

generative changes or even aneurysms around the area of coarctation. However, if the cardiac reserve is sufficient, the condition can be satisfactorily repaired well into mid-adult life. The mortality rate in this age group is about 5 per cent.

Associated valvular lesions producing severe hemodynamic changes greatly increase the hazards of surgery. Surgical treatment is probably contraindicated in the presence of severe aortic insufficiency, but not in mild insufficiency.

The operation of choice is excision of the area of coarctation and primary anastomosis. If the length of aortic constriction does not allow primary anastomosis, aortic grafts may be used (Gross). Sympathectomy is of no value in the treatment of hypertension due to coarctation. Anastomosis of the left subclavian artery and the aorta below the coarctation (Blalock and Park) has generally been abandoned.

After operation there is a striking improvement in the amplitude of pulsations in the femoral artery. Patients may note a definite increase in the temperature of their legs. Headaches and epistaxes disappear, and symptoms of cardiac failure are improved. The relief of hypertension may be delayed for three or four weeks. Murmurs may not disappear after operation; they are probably due to persistent enlargement of the collateral vessels or aortic valve disease.

Hypertension with abdominal pain may occur in the immediate postoperative period. The abdominal pain varies in severity and may subside without treatment. In other instances it is associated with anorexia, nausea, vomiting, leukocytosis and even signs of small bowel obstruction. These patients usually respond to therapy with antihypertensive drugs, but in some instances surgical treatment for intestinal obstruction is indicated. This complication is due to mesenteric arteritis, but its cause is unknown.

**Coarctation of the Aorta in Infancy.** In rare instances coarctation of the aorta is complicated by severe congestive cardiac failure during infancy. Gross suggests that failure at this early age is due to closure of the ductus arteriosus in the absence of a well developed collateral circulation; Nadas suggests that it results from severe degrees of coarctation at birth. Endocardial sclerosis is not infrequently associated with coarctation of the aorta and may also be the mechanism of the heart failure (Bonham-Carter). It is also apparent that

uncomplicated coarctation may produce heart failure in infancy.

Symptoms usually appear within the first three months of life. The infant is severely ill and irritable and has tachypnea. Heart failure is manifest by hepatomegaly, rales in the chest and increased venous pressure. Absent or weak femoral arterial pulsations contrast with normal or bounding radial pulses. The heart is greatly enlarged, and a systolic murmur over the whole precordium with gallop rhythm is frequent. Roentgen studies confirm the cardiac enlargement; the heart shape is globular. The electrocardiogram reveals left ventricular hypertrophy, frequently with T wave inversion over the left precordium. Right ventricular hypertrophy may be associated.

Vigorous therapy for congestive heart failure is indicated. This includes digitalis, mercurial diuretics, low-salt diet and oxygen. In the majority of instances there is a slow but definite response over a period of weeks. These patients tend to do well after infancy, and surgery is undertaken between the optimal ages of eight and fifteen years. Surgery is indicated during infancy only in rare instances.

#### COARCTATION OF THE AORTA AND PATENT DUCTUS ARTERIOSUS

Many anatomic and physiologic classifications have been devised in an attempt to describe the nature of these coexisting abnormalities. The anatomic classifications depend on the site and length of coarctation, the site of the aortic opening of the ductus and the size of the aorta proximal to the coarctation. The direction of blood flow across the ductus depends primarily on the pulmonary vascular resistance. In the majority of instances the pulmonary vascular resistance is lower than the systemic resistance, so that the shunt is from aorta to pulmonary artery. This occurs irrespective of the site of aortic opening of the ductus in relation to the coarctation. In these patients the signs of patent ductus arteriosus are superimposed on those of coarctation of the aorta, and both lesions may be treated surgically simultaneously.

In infancy a large patent ductus arteriosus entering below a coarctation may be associated with a high pulmonary vascular resistance. This results in a reversal of blood flow across the ductus, so that the aorta below the coarctation is supplied with venous blood from the pulmonary artery. In this age group

these lesions are associated frequently with other complex cardiac malformations such as endocardial sclerosis with or without mitral and aortic valvular disease, transposition of the aorta and pulmonary artery and ventricular septal defect. Symptoms occur early and include dyspnea, cyanosis, superimposed pulmonary infections and feeding difficulties. Congestive cardiac failure also occurs early. Because the descending aorta is supplied with venous blood, differential cyanosis may be expected with cyanosis below the pelvic brim and a normal color of the upper half of the body. Unfortunately this sign is not always conspicuous, even if carefully looked for. The femoral pulses are present, but are sometimes weak. Although the heart is enlarged, murmurs are not diagnostic. The murmur is systolic, is heard over the whole precordium and is usually followed by a loud second sound. The electrocardiogram shows right ventricular hypertrophy. Roentgen examination confirms the cardiac enlargement and also reveals increased pulmonary vascularity. The prognosis is usually poor, and therapy is symptomatic.

### ANOMALOUS PULMONARY VENOUS RETURN

Abnormal development of the pulmonary veins may result in their anomalous drainage into the systemic venous circulation. The position of abnormal entry may be into the right atrium, into the superior or inferior vena cava or one of their major tributaries or into a persistent left superior vena cava, which opens into the coronary sinus. Rarely, the pulmonary veins may enter the portal vein. An associated atrial septal defect is frequently present. All or only part of the pulmonary venous return may empty into the systemic venous circulation.

#### PARTIAL ANOMALOUS PULMONARY VENOUS RETURN

A varying number of pulmonary veins may enter the systemic venous circulation or right atrium. This results in a left-to-right shunt of oxygenated blood, which is enhanced if there is an associated atrial septal defect. Partial anomalous pulmonary venous return usually involves some or all of the veins of only one lung, more frequently the right. The history, physical signs, electrocardiogram and roentgen findings are indistinguishable from those of atrial septal defect (ostium secundum). Occasionally an anomalous vein

FIG. 272. Teleroentgenogram in partial anomalous pulmonary venous return with an atrial septal defect. Note the cardiac enlargement, prominent pulmonary artery and pulmonary overvascularity. (Compare with Fig. 273.)

is visible radiologically as a crescentic shadow of vascular density along the right border of the cardiac silhouette.

During *cardiac catheterization* the catheter may enter the anomalous pulmonary vein from the superior vena cava or right atrium or may traverse the associated atrial septal defect. The site of left-to-right shunt depends on the point of entry of the pulmonary veins and may be found in the superior vena cava or right atrium. Frequently the oxygen content and saturation of the caval and right atrial blood are indistinguishable from those of atrial septal defect. Dye dilution curves are valuable to demonstrate the presence of anomalous pulmonary veins. The indicator dye is injected first into one and then the other pulmonary artery, and the circulation time measured from the blood of a peripheral artery or with an ear oximeter. The lung with anomalous venous drainage has a significantly longer circulation time. Anomalous pulmonary veins may also be demonstrated by *selective angiocardiology*.

The *prognosis* is similar to that described under atrial septal defect (ostium secundum).

In symptomatic patients surgical *therapy* is indicated. This is usually undertaken during cardiopulmonary bypass or hypothermia. If there is an associated atrial septal defect, it should be closed in such a way as to direct the pulmonary venous return to the left atrium.

#### TOTAL ANOMALOUS PULMONARY VENOUS RETURN

There is no venous connection with the left atrium, and all the blood returning to the

heart (the systemic and pulmonary venous blood) enters and mixes in the right atrium. Some of the blood passes into the right ventricle and pulmonary artery, and the remainder passes through an atrial septal defect or patent foramen ovale to the left atrium.

Usually the pulmonary veins form a single trunk before entering the systemic venous circulation at one of the following sites: left superior vena cava (43 per cent), coronary sinus (19 per cent), right atrium (14 per cent) and right superior vena cava (12 per cent) (Keith et al.). The remainder enter the portal vein or ductus venosus.

Most often symptoms occur during the first two years of life and include tachypnea, poor weight gain and congestive heart failure. Cyanosis may not be definite in many patients, especially in early life, but in others the sign may be striking. The left side of the chest is frequently protuberant and the heart enlarged. On auscultation gallop rhythm is usual. In early life murmurs may not be audible, but in the majority of instances a systolic murmur is heard maximally down the left sternal border and may be followed by a diastolic murmur. A continuous murmur with the quality of a venous hum may be audible over the pulmonary area and sometimes under the right clavicle.

The *electrocardiogram* demonstrates right ventricular hypertrophy, and the P waves are frequently tall and spiked. The roentgen examination is pathognomonic if the pulmonary veins enter the innominate vein and persistent left superior vena cava (Fig. 273). It consists of a large supracardiac shadow producing a "figure-of-eight" or "snowman" appearance. The supracardiac shadow is produced by the dilated left superior vena cava, left innominate vein and right superior vena cava. If the pulmonary veins drain elsewhere, the heart is enlarged, the pulmonary artery and right ventricle are prominent, and the pulmonary vascularity increased.

*Cardiac catheterization* shows that the oxygen saturation of blood in both atria, both ventricles and the aorta is more or less similar and higher than that of peripheral systemic venous blood. In older patients the pulmonary arterial and right ventricular pressures may be only moderately elevated, but in infancy pulmonary hypertension is usual. The catheter may enter the left superior vena cava. *Selective angiocardiology* after injection of contrast medium into the pulmonary artery shows the anatomy of the pulmonary

FIG. 273. Teleroentgenogram in a patient with total anomalous pulmonary venous return, showing the "snowman" or "figure-of-8" configuration (see text).

veins and their point of entry into the systemic venous circulation.

The *prognosis* is usually poor, and survival beyond infancy is unusual; death is due to congestive heart failure. Patients who survive beyond two years of age may have surprisingly few symptoms. Surgical *treatment* is now possible and is undertaken preferably with the heart-lung machine. The common pulmonary venous trunk is anastomosed to the left atrium, the atrial septal defect is closed, and the connection to the systemic venous circuit is obliterated. Although the surgical results are good in older children, the risk is high in infancy.

## CONGENITAL AORTIC STENOSIS

Congenital aortic stenosis accounts for about 3 per cent of all cardiac malformations; it is more common in males (3:1). In the majority of instances the stenosis is valvular, the leaflets thickened and the commissures fused in varying degrees. In others the stenosis is subvalvular (subaortic) with a fibrous obstruction to the left ventricular outflow below the aortic valves.

Most often the child is asymptomatic, the physical development is good and the abnormality is discovered during routine physical examination. Fatigue and dyspnea are present in some patients. In contradistinction to aortic stenosis in adults, children seldom experience angina pectoris, syncope or left ventricular failure. The pulse is usually nor-

mal; it sometimes has a small volume, and it is anacrotic in the minority of patients. The heart size and apical impulses are usually normal. A coarse, harsh systolic ejection murmur, usually accompanied by a thrill, is audible maximally in the aortic area and radiates down the left sternal border and toward the apex. In some patients the systolic murmur may be maximal down the left sternal border or even at the apex. Diastolic murmurs are not infrequent. Concomitant aortic insufficiency produces an aortic blowing diastolic murmur, and in some patients an apical mid-diastolic rumbling murmur is audible in the presence of a normal mitral valve. The normal splitting of the second heart sound is usually present, but it may be single.

The electrocardiogram is frequently a reliable guide to the severity of the stenosis. If the gradient of pressure across the aortic valve is small, the electrocardiogram is normal. In severer cases there is evidence of left ventricular hypertrophy even with inversion of T in V<sub>6</sub>. Roentgen studies confirm that the cardiac size is unusually normal. The ascending aorta is frequently prominent, but the aortic knob is normal.

Right cardiac catheterization does not reveal any abnormalities. In severe cases the gradient across the aortic valve may be measured by the simultaneous recording of left ventricular and aortic or brachial artery pressures. Because the left atrium is normal in size, left ventricular pressures are usually obtained by direct left ventricular puncture.

The *prognosis* is good in the majority of children; however, in a small number sudden death, frequently precipitated by severe physical exertion, has been reported. In these patients there is usually evidence of gross left ventricular hypertrophy. The prognosis is also affected by associated malformations, including ventricular and atrial septal defects, coarctation of the aorta and pulmonary stenosis. A small group of patients with aortic stenosis succumb during infancy from congestive heart failure. In these patients associated endocardial sclerosis of the left ventricle and atrium and mitral valve may be found.

*Surgical treatment* is indicated in patients with dyspnea and fatigue and with electrocardiographic evidence of gross left ventricular hypertrophy. The aortic valvotomy is performed under direct vision during cardiopulmonary bypass or hypothermia. Postoperative evaluation is difficult, owing to the paucity of symptoms prior to surgery, and

because aortic insufficiency may be produced by the valvotomy. However, the electrocardiographic improvement with alleviation of the signs of left ventricular hypertrophy indicates that the gradient across the aortic valve has been abolished or improved. Surgery is not indicated in the absence of definite evidence of left ventricular hypertrophy. There is probably some danger in allowing these patients to participate in active competitive sport, but otherwise they should lead normal lives. The status of each patient should be reviewed annually, and surgery advised if progression of signs is definite. Since subacute bacterial endocarditis may develop in these patients, penicillin prophylaxis is indicated at the time of tonsillectomy, dental extractions and oral surgery.

### CONGENITAL MITRAL STENOSIS

This relatively rare anomaly is usually associated with other defects, the commonest ones being patent ductus arteriosus, aortic stenosis and coarctation of the aorta. The role of endocardial sclerosis in the etiology of this anomaly is not clear. The mitral valve is funnel shaped, its leaflets are thickened, and the chordae tendineae are shortened and deformed.

Symptoms usually appear within the first two years of life. The infants are underdeveloped and usually have obvious dyspnea, and cyanosis is not infrequent. Episodes of congestive heart failure are common. The heart is usually enlarged, owing to dilatation and hypertrophy of the right ventricle. Although a variety of murmurs have been described (mainly systolic in time), our four cases all had rumbling diastolic murmurs followed by a loud first sound. The second sound is loud and split. The electrocardiogram reveals right ventricular hypertrophy, with normal, bifid or spiked P waves. Roentgen studies usually show generalized cardiac enlargement, pulmonary congestion and increased hilar markings. Cardiac catheterization demonstrates an increase in right ventricular, pulmonary artery and pulmonary wedge pressures and may also demonstrate the presence of such associated anomalies as patent ductus arteriosus. Angiocardiography may show delayed emptying of the left atrium.

The *prognosis* is usually poor; the majority of children succumb during the first two years of life. *Surgical treatment* has been attempted, but the results have been poor.

## ANOMALIES OF THE AORTIC ARCH

### RIGHT AORTIC ARCH

In this abnormality the aorta curves to the right and descends on the right side of the vertebral column; it is usually associated with other cardiac malformations. It is found in 20 per cent of cases of tetralogy of Fallot and is common in truncus arteriosus. A right aortic arch without other anomaly is asymptomatic. It can be demonstrated roentgenographically; the aortic arch is delineated to the right of the sternum. The barium-filled esophagus is indented on its right border at the level of the aortic arch.

### VASCULAR RINGS

Congenital abnormalities of the aortic arch and its major branches result in the formation of vascular rings around the trachea and esophagus with varying degrees of compression on these structures. The following are the more common anomalies: (1) double aortic arch (Figs. 274, 275), (2) right aortic arch with left ligamentum arteriosum, (3) anomalous right subclavian artery arising as the last major thoracic branch of a normally placed aorta (Fig. 276), (4) anomalous innominate artery arising further to the left on the arch than usual, (5) anomalous left carotid artery arising further to the right than usual and passing anterior to the trachea.

The clinical patterns are extremely variable. In some instances, and especially with anomalous right subclavian artery, the condi-

tion is asymptomatic. If the vascular ring produces compression of the trachea and esophagus, symptoms are frequently present during infancy. Respirations are wheezing in quality and aggravated by crying, feeding and flexion of the neck. Extension of the neck tends to relieve the noisy respiration. Vomiting is frequent. There may be a brassy cough, and complicating pneumonia is common. The diagnosis is established by examination of the barium-filled esophagus during fluoroscopy and on roentgenograms (Figs. 275, 276) and by observation of the air- or Lipiodol-filled trachea.

Surgery is advised in symptomatic patients with radiographic evidence of tracheal and/or esophageal compression. The appropriate vessel is divided in patients with double aortic arch (Fig. 274). Compression produced by a right aortic arch and left ligamentum arteriosum is relieved by division of the latter. An anomalous right subclavian artery is divided at its origin from the aorta. Anomalous innominate or carotid arteries cannot be divided; the tracheal compression is relieved by attaching the adventitia of these vessels to the sternum.

### ANOMALOUS ORIGIN OF CORONARY ARTERIES

**Anomalous Origin of the Left Coronary Artery from the Pulmonary Artery.** In this condition the arterial blood supply to the left myocardium is from the pulmonary artery (venous blood at a low perfusion pressure).

FIG. 274. Double aortic arch. A, Small anterior segment of double aortic arch (most common type). B, Operative procedure for release of vascular ring. (Courtesy of Dr. Willis J. Potts.)

FIG. 275. Double aortic arch in an infant aged 5 months. *A*, Anteroposterior view. The barium-filled esophagus is constricted on both sides. *B*, Lateral view. The esophagus is displaced forward. The anterior arch was the smaller and was divided at operation. (Courtesy of Drs. Eugene Saenger, Frederick Silverman and Edward McGrath.)

FIG. 276. Esophagram of a child with aberrant origin of the right subclavian artery as a last branch from the arch of the aorta. The positions from left to right are lateral, left anterior oblique, right anterior oblique, anteroposterior. A constant defect is visualized on the posterior aspect of the esophagus.

The right coronary artery becomes enlarged, and collateral channels may result in a reverse flow in the abnormal left coronary artery (Keith, Rowe and Vlad). The left ventricle becomes dilated and somewhat hypertrophied with patchy fibrosis and microscopic deposition of calcium.

In the majority of instances symptoms

occur during the first few years of life, and are those of congestive heart failure, frequently associated with or precipitated by respiratory infections. Irritability and discomfort, sometimes aggravated by feeding could be interpreted as being produced by angina pectoris. Cardiac enlargement is moderate to marked, but murmurs are insignifi-

cant. Roentgen examination confirms the cardiomegaly, but the contour and pulsations are not specific unless there is a complicating ventricular aneurysm. The electrocardiogram resembles the pattern described in anterior myocardial infarction in adults. A QR pattern followed by inverted T waves is seen in standard lead I and aVL. The left ventricular surface leads ( $V_5$  and  $V_6$ ), show deep wide Q waves and may also exhibit elevated S-T segments and inverted T waves. The diagnosis may be established by selective angiocardiology when injection of contrast material into the pulmonary artery demonstrates the origin and distribution of the abnormal left coronary artery. The large right coronary artery may be visualized by retrograde aortography.

In the majority of instances death from heart failure occurs within the first few years of life, although there are some reported cases of survival into adult life. Treatment is symptomatic. Surgical transplantation of the origin of the left coronary artery to the aorta is being investigated.

**Anomalous Origin of Both Coronary Arteries from the Pulmonary Artery** is extremely rare and may be associated with other severe cardiac malformations. The prognosis is usually poor.

**Anomalous Origin of the Right Coronary Artery from the Pulmonary Artery** is also rare, but does not produce signs or symptoms. The prognosis is good, and the condition is found as an incidental pathologic entity.

## PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension is a disease of unknown etiology characterized by hypertension of the lesser circulation and right-sided heart failure. The disease may occur at any age and may be clinically recognizable during childhood and adolescence. The pulmonary hypertension is associated with sclerosis of the pulmonary arteries and arterioles, thickening of the intima, atheromatous deposits and thromboses. Other causes of pulmonary heart disease (chronic cor pulmonale) are absent, and there is no evidence of emphysema, pancreatic fibrosis or kyphoscoliosis. Recurrent pulmonary emboli may produce the same clinical picture, but this disease is rare in childhood.

**Hemodynamics.** The pulmonary hypertension places a mechanical burden on the right ventricle and pulmonary artery with resultant right ventricular hypertension and dilatation

of the pulmonary artery. Sooner or later right-sided heart failure develops, at times with tricuspid insufficiency.

**Clinical Manifestations.** The predominant symptom is increasing dyspnea on effort. Peripheral cyanosis may be present and is associated with cold extremities and a nearly normal arterial oxygen saturation. If right-sided heart failure has supervened, the jugular venous pressure is elevated, and there are hepatomegaly and edema. Jugular venous "a" waves are present and, if functional tricuspid insufficiency has supervened, a conspicuous jugular "c" wave develops with systolic hepatic pulsations. The heart is slightly to moderately enlarged with a right ventricular apical tap. Thrills are absent, and murmurs may be insignificant. A grade 1 systolic murmur may be audible over the pulmonary area, sometimes followed by a blowing diastolic murmur due to pulmonary incompetence. The second heart sound is normally split and accentuated, and presystolic gallop rhythm may be audible down the left sternal border.

*Roentgen studies* reveal a prominent pulmonary artery and right ventricle (Fig. 277). The pulmonary vascularity in the hilar areas may be normal, but the peripheral lung fields are clear. The *electrocardiogram* shows right ventricular hypertrophy with spiked P waves. The diagnosis is confirmed by *cardiac catheterization*, which reveals right ventricular

FIG. 277. Teleroentgenogram in primary pulmonary hypertension, showing moderate cardiac enlargement, pulmonary artery dilatation and relative pulmonary undervascularity in the outer two thirds of the lung fields. This roentgen picture may simulate that found in valvular pulmonic stenosis with normal aortic root.

and pulmonary hypertension with a normal pulmonary "capillary" pressure. The cardiac output is usually low, and the arterial oxygen saturation is nearly normal.

Difficulty may arise in differentiating this condition from isolated pulmonary stenosis. In primary pulmonary hypertension a thrill is absent, murmurs are not significant, and the second sound is normally split. Cardiac catheterization excludes the presence of pulmonary stenosis. If primary pulmonary hypertension is associated with a reversed intratrial shunt through a foramen ovale, the clinical picture may simulate that of the Eisenmenger syndrome.

The disease is progressive, and the results of treatment are disappointing. Some relief may be obtained by the usual measures adopted for congestive cardiac failure.

### MARFAN'S SYNDROME—

#### CARDIOVASCULAR MANIFESTATIONS

The frequent site of involvement in the cardiovascular system in the Marfan syndrome (p. 1243) is the ascending aorta. Aortic dilatation begins at the aortic valve

ring and is usually confined to the ascending aorta. The valve ring is stretched, and the resultant aortic insufficiency may be pronounced. Progressive left ventricular failure occurs with or without angina pectoris. Dissecting aneurysm of the aorta is a common terminal event or may result in the development of aortic valve incompetence. Cardiac symptoms may occur as early as the fifth year of life, but frequently do not appear until adult life.

The pulmonary artery and valve may be involved in a similar way to that of the aorta, resulting in dilatation of the pulmonary artery. This syndrome may explain some cases of *idiopathic pulmonary artery dilatation*. Mitral insufficiency may result from redundant cusps and chordae tendineae. Subacute bacterial endocarditis may be a complication.

The frequency of congenital malformations of the heart in the Marfan syndrome probably has been overstressed. The reported conditions include atrial septal defect, rarely ventricular septal defect, tetralogy of Fallot, patent ductus arteriosus and coarctation of the aorta.

## PRINCIPLES OF TREATMENT IN CONGENITAL HEART DISEASE

The following principles of treatment apply to all patients with congenital heart disease. Owing to rapid advances in the diagnosis and surgical treatment of these anomalies, an attitude of guarded optimism should be adopted. A level of life as nearly normal as possible should be encouraged because untold psychologic trauma is imposed by unnecessary restriction. The parents' attitude toward the child is commonly more relaxed if it is pointed out that sudden death is rare in congenital heart anomalies in contradistinction to some degenerative diseases in adults. Rigorous restriction of physical activities is usually not indicated, since children soon learn their own capacity for exercise. However, if cardiac enlargement is present or there is a history of frank congestive heart failure, competitive sports should be discouraged.

General management includes a well balanced diet, the supplementation of iron and vitamins during the first few years of life and the usual immunization program.

The prevention or prompt treatment of dehydration in cyanotic patients is important so that hemoconcentration and possible

thrombotic episodes will be averted. Infections should be vigorously treated with suitable antibiotics to prevent the onset of subacute bacterial endocarditis or congestive heart failure. The routine use of sulfadiazine, oral penicillin or other antibiotics may be indicated in patients prone to recurrent respiratory infections. Nadas and Rudolph have shown that within limits correction with iron therapy of a "relative hypochromic anemia" in cyanotic patients may improve their exercise tolerance and general well-being. The treatment of congestive heart failure and of paroxysmal dyspneic attacks has been described elsewhere.

**Surgical Treatment.** The standardized surgical therapy of patent ductus arteriosus, coarctation of the aorta and vascular rings has been described elsewhere. The following résumé of open-heart surgery is included because of the widespread successful use of this technique. This complex surgical therapy should not be undertaken until the surgical team has had a successful and wide experience with animals and the physiology of total body perfusion is understood clearly.

**Open-heart surgery.** This technique is used

when surgical treatment of intracardiac defects under direct vision is indicated. The systemic venous return to the heart is diverted to an artificial heart-lung machine, and arterialized blood is returned to the systemic arterial system (*cardiopulmonary bypass*). Thus the major source of blood flow through the heart and lungs is diverted, and the chambers of the "bloodless" heart may be opened widely. The systemic venous return to the heart is picked up by cannulae in the superior and inferior venae cavae usually inserted through the right atrium. The arterialized blood is returned from the heart-lung machine to either the femoral or left subclavian artery. In the former instance the body is perfused in a retrograde direction. With this system of cannulation coronary and bronchial flows are not disturbed, and the heart continues to beat. If it is desired to abolish coronary flow and cardiac contraction during cardiopulmonary bypass, this may be accomplished by the production of *elective cardiac arrest*. This is achieved by cross clamping the ascending aorta, and injecting a "cardioplegic" agent into the aorta so that it enters the coronary circulation.

**Heart-lung machines.** There are a variety of machines to oxygenate the blood, remove an adequate amount of carbon dioxide and pump optimal volumes of arterialized blood back into the patient. These include the following:

**BUBBLE OXYGENATORS.** Oxygen bubbles are allowed to mix directly with the venous blood. The excess gas (mainly oxygen) is coalesced on a polymethylsiloxane surface and removed.

**SURFACE OXYGENATORS.** Venous blood is spread as a thin film on either screens or disks and exposed to oxygen gas.

**MEMBRANE OXYGENATORS.** Membranes permeable to the flow of oxygen and carbon dioxide are placed between the venous blood and the oxygen. Blood is arterialized by the passage of respiratory gases across the membrane.

**The postoperative period.** With successful total body perfusion and direct-vision open-heart surgery, the postoperative course is frequently benign. However, many of these patients may be in a delicate or precarious state. The following complications are listed as a guide to management:

**PLEURAL SPACE COMPLICATIONS.** Pneumothorax and hemothorax are treated along usual lines.

**PULMONARY COMPLICATIONS.** These consist of patchy areas of pulmonary atelectasis with or without edema and hemorrhage. It appears that these complications occur more frequently in patients with pulmonary hypertension and elevated pulmonary resistance. Decompression of the pulmonary vascular tree by cannulation of the left atrium during cardiopulmonary bypass probably decreases the severity of this complication.

**PULMONARY VENTILATION.** Respiratory exchange may be enhanced by the use of tracheotomy and respirators.

**HEMORRHAGE.** Although surgery is conducted in a heparinized state, postoperative bleeding should not be a problem. If it occurs, it may be an expression of inadequate perfusion.

**COMPLETE HEART BLOCK.** This distressing complication is probably produced by surgical trauma to the conduction system during the intracardiac procedure. If the ventricular rate is not adequate, the heart block is treated with isopropylarterenol (Isuprel) intravenously or by the use of a pacemaker. The latter apparatus may be applied externally, but recent reports indicate that better results are obtained by applying the electrical stimulus to wires which have been imbedded in the myocardium. The ultimate prognosis of surgically induced complete heart block is unknown. Spontaneous reversal to sinus rhythm may occur, but death from Stokes-Adams attacks is possible. Digitalis is not contraindicated in the presence of complete heart block.

**CONGESTIVE HEART FAILURE.** This may occur in the immediate postoperative period. Treatment is described elsewhere. We have not used digitalis in all patients preoperatively, but have reserved it for patients who show signs of congestive heart failure.

**ACIDOSIS.** Minor degrees of respiratory acidosis are common and do not require therapy. Severe metabolic acidosis may occur and is usually an indication of inadequate blood flow during cardiopulmonary bypass. It requires treatment (see p. 191).

## DISTURBANCES OF RATE AND RHYTHM OF THE HEART

**SINUS ARRHYTHMIA****(RESPIRATORY ARRHYTHMIA)**

This rhythm, characterized by an acceleration of the pulse rate during inspiration and a decrease during expiration, is physiologic in childhood. It is usually associated with cardiac rates under 90 to 100 per minute. It is exaggerated during convalescence from febrile illness and by drugs which increase vagal tone, such as digitalis, and is usually abolished by exercise or atropine. Some children have such great degrees of sinus arrhythmia that the presence of other arrhythmias such as extrasystoles is suspected, and an electrocardiogram is necessary for diagnosis.

**EXTRASYSTOLES****(PREMATURE CONTRACTIONS)**

Extrasystoles are produced by the discharge of an ectopic focus situated anywhere in atrial, nodal or ventricular tissue. They occur less

frequently in children than in adults. In the majority of instances extrasystoles are of no clinical or prognostic significance. Under certain circumstances, however, premature beats may be due to organic heart disease, e.g., in acute rheumatic or diphtheritic carditis. Drugs, especially digitalis and epinephrine, may also produce extrasystoles. Atrial premature contractions may precede atrial fibrillation in rheumatic heart disease with mitral stenosis.

The clinical signs of extrasystoles include the prematurity of the beat followed by a compensatory pause, especially if the ectopic beat arises in the ventricles. In the majority of instances extrasystoles disappear during the tachycardia of exercise. If they remain or become exaggerated during exercise, it suggests that they are associated with organic heart disease. Ectopic beats produce a smaller stroke and pulse volume than normal and, if very premature, may not be audible with a stethoscope or palpable at the radial pulse. Extrasystoles may assume a definite rhythm,

e.g., alternating with normal beats (*pulsus bigeminus*) or occurring after two normal beats (*pulsus trigeminus*). This rhythmicity is frequent in digitalis intoxication. The site of origin of the extrasystoles is determined by the electrocardiogram.

Most patients are unaware of premature contractions. The basis of therapy is convincing reassurance that the arrhythmia is not due to structural heart disease. If extrasystoles are produced by digitalis, the drug should be discontinued or its dose reduced. If relief is sought for palpitations, sedatives, quinidine sulfate or procaine amide may be used.

### PAROXYSMAL TACHYCARDIA

Paroxysmal tachycardia is produced by ectopic beats arising from the same focus in rapid succession. The ectopic focus may be situated anywhere in the atrial, nodal or ventricular tissue. Paroxysmal tachycardia may occur at any age and has been reported in the last month of fetal life. In the majority of instances the ectopic focus is situated in an atrium (paroxysmal atrial tachycardia). Paroxysmal ventricular or nodal tachycardia is rare in infants and children.

In older children attacks of paroxysmal atrial tachycardia are characterized by abrupt onset and cessation. If an attack is not witnessed, its occurrence may be elicited by an accurate history. The attacks may last from a few seconds to several weeks, but usually persist for a few hours and seldom exceed two or three days. The cardiac rate usually exceeds 180 and occasionally may be as rapid as 300 per minute. Sometimes the attack is precipitated by an acute infection. In many instances the patient feels well, and the only complaint is consciousness of the rapid cardiac rate. If the cardiac rate is exceptionally rapid or if the attack is prolonged, precordial discomfort and congestive cardiac failure may supervene.

In young infants the diagnosis may be more obscure. Since the normal cardiac rate at this age is rapid and increases greatly with crying, a persistent tachycardia during quiet periods or sleep suggests the diagnosis. The cardiac rate during paroxysms is frequently in the range of 300 per minute, and signs of congestive cardiac failure rapidly supervene if the attack lasts a few hours or more. The infant is acutely ill, has an ashen and slightly cyanotic color and is restless and irritable. Tachypnea and hepatomegaly are the prominent signs of cardiac failure. Paroxysms may

LEAD I

LEAD I

FIG. 278. Electrocardiogram in paroxysmal atrial tachycardia. Upper tracing taken during paroxysm with heart rate of 215 per minute. Lower tracing, taken during recovery, is within normal limits.

be associated with fever and leukocytosis. The diagnosis is confirmed by the electrocardiogram (Fig. 278), which also identifies the site of the ectopic focus.

**Treatment.** In supraventricular paroxysmal tachycardia (atrial or nodal) simple procedures of vagal stimulation such as pressure over the eyeball or unilateral carotid sinus may abort the attack. Older children may have discovered some maneuver to abolish the paroxysm, such as self-induced vomiting, breath-holding, drinking iced water or the adoption of a particular posture. In infants and many older patients these measures fail, and digitalis should be given in full therapeutic doses if the attack persists for four to eight hours and if congestive cardiac failure has supervened. Sedation is also indicated. In the infrequent instances in which digitalis does not stop the paroxysm, quinidine sulfate or a cholinergic drug such as neostigmine or Mecholyl (acetyl-beta-methylcholine) may be used. Mecholyl may produce side effects of vomiting, sweating, faintness, colic, urgency of micturition and defecation and sometimes cardiac arrest. Atropine sulfate should be available to counteract these side effects. The drugs of choice in paroxysmal ventricular tachycardia are intravenously administered procaine amide or parenteral quinidine sulfate. If attacks occur frequently, digitalis therapy should be maintained, or quinidine sulfate may be continued indefinitely if it is well tolerated.

FIG. 279. Electrocardiographic pattern of the Wolff-Parkinson-White syndrome in a 6-year-old boy. The P-R interval is 0.08 second; the duration of the QRS interval, 0.12 second.

In most instances of paroxysmal atrial tachycardia there is no underlying structural cardiac disease. If cardiac failure supervenes during the paroxysms, cardiac function rapidly returns to normal after cessation of the attack. Between attacks some children may exhibit the electrocardiographic signs of the *Wolff-Parkinson-White syndrome*, which is probably due to an anomalous connection by special conducting fibers between the right atrium and the ventricles. Electrocardiography shows a widened QRS complex at the expense of a shortened P-R interval so that the P-S interval as measured from the beginning of the P to the end of the S is normal (Fig. 279). In the majority of instances there is no associated cardiac disease. Paroxysmal atrial tachycardia occurs in about 50 to 60 per cent of patients with the Wolff-Parkinson-White syndrome, and about 5 per cent of patients with paroxysmal tachycardia will exhibit this syndrome between attacks of tachycardia.

## ATRIAL FLUTTER

This arrhythmia is due to rapid and regular but abnormal atrial contractions. Lewis attributed these contractions to a circus movement in the atria; Prinzmetal has suggested that they are due to an irritable focus in the atrial muscle similar to that of paroxysmal atrial tachycardia and atrial extrasystoles. The rate of atrial beats ranges between 250 and 400 per minute. Because the atrioventricular node cannot transmit these rapid impulses, the ventricles respond to every second atrial beat or sometimes to every third or fourth one.

Atrial flutter is not frequent in children, but may sometimes complicate myocarditis of any cause and occasionally acute infectious diseases. The abnormality should be suspected in patients with a regular tachycardia which is not influenced by effort, emotion or posture. Atrial flutter may precipitate congestive cardiac failure. Carotid sinus pressure frequently produces a temporary slowing of the cardiac rate. The diagnosis is confirmed by electrocardiography, which demonstrates the rapid and regular atrial flutter, "f" waves.

*Treatment* is by digitalizing to convert the arrhythmia into atrial fibrillation. Normal sinus rhythm may then be restored when the digitalis is discontinued. If atrial fibrillation persists, quinidine sulfate is used to establish normal rhythm. If atrial flutter continues in spite of this latter treatment, the administration of digitalis is resumed.

## ATRIAL FIBRILLATION

The mechanism of this abnormality is similar to that described under Atrial Flutter except that the atrial excitation is irregular and more rapid (300 to 500 per minute). The arrhythmia occurs most frequently in older children with chronic rheumatic heart disease and mitral stenosis. It is rare in congenital heart disease, but has been reported as a complication of atrial septal defect and patent ductus arteriosus.

The characteristic sign is a grossly irregular cardiac rhythm (Fig. 280) associated with a pulse deficit. Atrial fibrillation may complicate or precipitate congestive cardiac failure.

FIG. 280. Electrocardiogram of an 11-year-old girl with rheumatic heart disease and mitral stenosis. The tracing reveals the presence of atrial fibrillation.

All patients should be treated with full doses of digitalis until the cardiac rate returns to normal limits. Normal sinus rhythm may be restored if the patient is treated with quinidine sulfate after digitalization.

### VENTRICULAR FIBRILLATION

This is an irregular ventricular action (Fig. 281) resulting in death unless an effective ventricular beat is restored. Occasionally this arrhythmia occurs during or shortly after cardiac surgery and explains some of the deaths due to intravenous drug therapy. The only effective therapy is cardiac massage and electrical defibrillation.

### BRADYCARDIA

A slow pulse rate may occur during convalescence from acute infections such as rheumatic fever, typhoid fever or infectious hepatitis and in association with lesions of the brain which cause increased intracranial pressure. Older children and young adults who lead active lives frequently have pulse rates of about 60 per minute at rest. Bradycardia of this degree may occur as a family trait. Rates of less than 80 per minute in the first two years of life and less than 60 in older children may be due to heart block.

FIG. 281. Electrocardiogram tracings showing various types of arrhythmias. Upper tracing shows the Wenckebach phenomenon. Note progressive prolongation of the P-R interval. Middle tracing shows idioventricular rhythm with a heart rate of 30 per minute. Lower tracing shows ventricular fibrillation.

### HEART BLOCK

The conductive system includes the sino-atrial node (SA node), the atrial muscle, the atrioventricular node (AV node), the bundle of His with its left and right branches, and the Purkinje network. The conductive system may be blocked at any site along this pathway. When the block occurs at the sino-atrial node so that occasional beats are delayed or dropped, it is designated *sino-atrial block*. When the impulse is blocked in its pathway from the sino-atrial node through the atrioventricular node, it is termed *atrioventricular block* (AV block). *Partial atrioventricular block* may have only prolonged P-R interval (*first-degree block*) or may be associated with dropped ventricular beats (*second-degree block*). Second-degree block may occur at regular intervals so that there are two or three atrial beats to one ventricular beat (2:1 or 3:1 partial atrioventricular block). Another type of partial atrioventricular block is a progressive lengthening of the P-R interval from cycle to cycle until a ventricular beat is dropped (*Wenckebach phenomenon*, Fig. 281). When no impulses pass through the atrioventricular node so that the atria and ventricles contract independently of each other, the condition is known as *complete atrioventricular block*. Finally the impulse may be blocked in either the left or right branch of the bundle of His, and the condi-

tion is designated as *left* or *right bundle branch block*.

Complete heart block and first-degree partial block are the common types encountered in children.

### CONGENITAL COMPLETE HEART BLOCK

In children complete block is probably the result of a congenital defect in the main stem of the bundle of His. Atrial or ventricular septal defects may be associated lesions, although it is doubtful whether these defects in themselves cause an interruption of the conductive pathways which produce the block. In the embryo the conduction fibers are developed in the muscular tissue of the heart before the formation of the septa, and it would appear that a common etiologic factor which inhibits the normal development of the bundle of His also affects the cardiac septa. However, the majority of patients with atrial or ventricular septal defects have normal cardiac rhythms, and heart block usually occurs in patients with intact septa.

The condition is commonly asymptomatic, although attacks of syncope may occur. Congenital heart block is suspected if the cardiac rate is less than 80 in infants or less than 60 in older children. On this basis the condition has been occasionally suspected in the fetus several weeks before birth. The peripheral pulse is of the water-hammer type, owing to the large ventricular stroke volume and peripheral vasodilatation, and the systolic blood pressure is elevated. Jugular venous pulsations occur irregularly and may be large when the atrium contracts against a closed tricuspid valve. Inconspicuous venous pulsations may occur independently of ventricular contractions. The first cardiac sound has a changing intensity, and isolated atrial contractions may be audible down the left sternal border or at the apex. Taussig has observed that exercise and atropine, which have no effect in increasing the cardiac rate of adults with complete heart block, may produce an acceleration of 10 to 20 beats per minute in the child. Heart block in itself does not produce cardiac enlargement. Left sternal border systolic murmurs are frequent and do not indicate the presence of a ventricular septal defect. Apical mid-diastolic murmurs are not unusual.

FIG. 282. Electrocardiogram of 5-year-old boy showing complete heart block (see text).

The diagnosis is confirmed by electrocardiograms which reveal that the P waves and QRS complexes have no constant relationship to each other (Fig. 282). The shape and amplitude of the individual waves are generally normal.

The *prognosis* is usually favorable, and a number of patients who have been followed up to the age of thirty to forty years have lived normally active lives except for occasional attacks of syncope. *Treatment* is guided toward encouraging an active and normal life. The following may be used in treatment of the rarely occurring syncopal attacks: ephedrine, isopropylarterenol (Isuprel) or external pacemakers.

# DISEASES OF THE ENDOCARDIUM

## ACUTE OR MALIGNANT ENDOCARDITIS

Acute endocarditis is rare during childhood, but has been observed at all ages, including the newborn period, when it may have been acquired during fetal life. The infection may occur suddenly in a previously well child or may develop during the course of some other illness. Occasionally it occurs as a complication of congenital or rheumatic heart disease. The bacteria most frequently found in the lesions are the *Streptococcus* and *Pneumococcus*, but others such as the *Staphylococcus*, *Gonococcus* and *Hemophilus influenzae* may be the infecting organisms. Vegetations of various sizes develop on the endocardium of the valves and cardiac chambers, more frequently on the left side than on the right. They consist of large numbers of bacteria growing in an exudate of fibrin and blood. Ulceration and the formation of a friable granulation tissue occur later, and the destructive process may extend to the muscle layers beneath the endocardium, causing fragmentation of the muscle fibers and hemorrhage. Parts of the vegetations or necrotic tissue may break off at any time and be carried to other regions of the body where they are caught in small blood vessels, obstructing blood flow beyond that point and establishing secondary foci of infection.

**Clinical Manifestations.** The symptoms of acute endocarditis are indefinite at first; high fever, usually remittent, may be the first indication. The cardiac rate is rapid, and the patient becomes prostrated. Septic emboli lodging in various organs may cause symptoms such as abdominal pain, hematuria, diarrhea, or paralysis of parts of the body. Murmurs are either absent or limited to soft systolic ones in the midcardiac or apical area. Blood cultures are usually positive, and the disease must be differentiated from other septicemias not involving the heart.

**Prognosis.** The prognosis is generally grave, and death usually occurs within a few weeks unless treatment is started early in the course of infection.

**Treatment.** Antibiotics selected on the basis of the sensitivity of the infecting organism to them should be prescribed in large doses. Supportive therapy, including the use of blood transfusions and intravenous fluids, is the same as for other acute infections.

## SUBACUTE BACTERIAL ENDOCARDITIS

This disease resembles the acute form in many ways, but its course is more protracted. The infection often develops at the site of congenital or acquired defects of the heart, and the common causative organisms are *Streptococcus viridans*, other types of streptococci, staphylococci and *Escherichia coli*. It rarely occurs in infancy, but has been noted occasionally in children three or four years of age; the incidence increases with advancing age. In a series of 181 patients with congenital heart disease who were over two years of age at the time of death, 16.5 per cent had subacute bacterial endocarditis (Gelfman and Levine). About 5 per cent of patients with rheumatic fever acquire the disease after an average period of ten to fifteen years.

The vegetations are usually smaller than those in the acute types, but resemble them in structure. They may destroy the endocardial lining and underlying muscle and may even perforate valves or septa of the heart. When superimposed upon acquired cardiac disease, the subacute form attacks the left rather than the right side of the heart, so that the mitral and aortic valves are involved more frequently than the pulmonic or tricuspid ones. In congenitally malformed hearts the bacterial invasion begins at the site of the defect, such as the border of a perforated septum, the constricted or stenotic part of the pulmonary artery or aorta, or at the pulmonary terminus of a patent ductus arteriosus.

**Clinical Manifestations.** The symptoms are obscure at first, consisting only in the daily rise in temperature characteristic of any septic condition. Moderate degrees of malaise and prostration tend to occur, and a rapidly developing anemia produces pallor. Anorexia and loss of weight have been early symptoms in some children. After a few days or weeks emboli from the vegetations lodge in various parts of the body and produce symptoms referable to the tissue involved. Among the first embolic signs are the reddish-purple petechiae, which appear in the skin or mucous membranes, and the raised nodules in the soft tissue at the ends of the fingers (Osler's nodes). Linear hemorrhages under the fingernails are characteristic, and in long-

continued infections clubbing of the fingers may develop. Abdominal pain suggests infarction of the spleen or some other abdominal organ; blood in the stool or urine indicates involvement of the intestinal or urinary tract. Enlargement of the spleen from numerous infarctions is a common sign. Hemiplegia and other nervous symptoms denote involvement of the brain or cord and provide a warning of impending death. The high degree of toxicity, which develops late in the disease, may be responsible for the hemorrhagic tendency, some of the nephritic symptoms and the severe prostration and fatigue. Murmurs are those of the underlying congenital or rheumatic lesion. Occasionally a soft systolic murmur at the apex is noted early in the disease and changes to a louder, harsher murmur as the disease progresses.

**Diagnosis.** Anemia and leukocytosis are common, but the most important finding in addition to the characteristic clinical signs is a positive blood culture. A number of samples of blood may have to be examined before the causative organism is isolated. In any child with congenital or acquired heart disease who suddenly has fever, subacute bacterial endocarditis may be developing, and repeated blood cultures should always be obtained. Cultures should be saved at least two weeks before a final negative report is given.

**Prognosis.** The prognosis has changed completely since the advent of antibiotics. Whereas in the past recovery was not to be expected, now most children recover completely. Children seem less likely to have cardiac failure than do adults, and they respond more rapidly to treatment. However, the disease runs such a mild course during its first weeks or even months that the diagnosis may not be suspected until suddenly there develops a fulminating course, resulting in death. If therapy is inadequate, recurrences may take place. A child must be free from evidences of the disease for at least two years before recovery can be said to be permanent.

**Treatment.** Penicillin is effective against most strains of the common infecting organisms. There are, however, notable differences in the relative susceptibility of various bacteria. For this reason it is desirable to know the sensitivity in vitro of the infecting organism. Therapy need not be delayed until the sensitivity of the organism is known, but it is advantageous to have secured the organism before therapy is started, so that sensitivity tests can be made. In rare instances the child may be in such a serious condition and

the diagnosis seem sufficiently obvious that delay in starting therapy is not justified, but blood for culture should be obtained initially. When the sensitivity of the organism is known, sufficient amounts of penicillin should be given to exceed the susceptibility level in vitro for at least part of the time between the individual injections. When the sensitivity of the organism is not known, the dosage must be gauged by the clinical response and by culture of the blood. As a rule daily doses of 2 to 3 million units of penicillin are required. Streptomycin is used in addition to penicillin, especially in infections with *Streptococcus viridans* even if studies in vitro indicate that the organism is not sensitive to streptomycin. There are no accurate means for determining how long therapy should be continued after the child has become fever-free and the blood cultures have become negative. In many instances a two-week course of therapy with penicillin and streptomycin has been curative. In other patients there is some justification for extending therapy for four to eight weeks. From that time on, for at least two years, he should be observed frequently and blood cultures obtained to make certain that he has recovered entirely. Some children whose symptoms do not abate quickly or whose blood cultures remain positive for a long time may need as much as 10 to 15 million units of penicillin per day for four to six weeks. If the causal organism is highly insensitive to penicillin, sensitivity tests in vitro may suggest the antibiotic or combination of antibiotics of choice. In all instances bacteriocidal drugs are preferable.

**Prophylaxis.** All children with rheumatic heart disease and congenital cardiovascular anomalies (especially of the acyanotic group) are exposed to the hazard of subacute bacterial endocarditis. Therefore these patients should be protected with large doses of penicillin for forty-eight hours before and after operations on the ears, nose or throat and dental extractions. Acute infections should be vigorously treated with suitable antibiotics to prevent the onset of subacute bacterial endocarditis.

## RHEUMATIC ENDOCARDITIS

Rheumatic infections (p. 903) are, of course, not limited to the endocardium, but involve other parts of the heart and other organs of the body; only the endocardial changes will be mentioned here.

Rheumatic involvement of the valves and

endocardium is by far the most common type of endocarditis in children. The lesions begin as small verrucae composed of fibrin and blood cells along the borders of the valves. The mitral valve is affected most often, the aortic next most frequently, and the tricuspid and pulmonary valves less commonly. As the infection subsides, the verrucae tend to disappear and leave scar tissue. With each repeated infection more small lesions of this type form near the previous ones, and the mural endocardium and chordae tendineae also become involved.

#### Clinical Patterns of Valvular Disease.

**Mitral insufficiency.** Organic mitral insufficiency which prevents normal closure of the mitral valve is most frequently rheumatic in origin. There is usually some loss of substance of the mitral valve, and the chordae tendineae may be shortened and thickened. There is often associated mitral stenosis due to sclerosis of the base of the mitral ring and cusps.

During ventricular systole, blood regurgitates from the left ventricle to the left atrium. This may result in left atrial enlargement, which is sometimes aneurysmal. Owing to the greater work load and filling pressure of the left ventricle, this chamber may also enlarge. The increased left atrial pressure may be reflected through the pulmonary bed to the right heart, producing enlargement of the right ventricle and atrium, with subsequent congestive cardiac failure.

The pulse, blood pressure and the jugular venous pressure are normal. Cardiac enlargement may be present and depends on the degree of mitral insufficiency and associated myocarditis. An apical systolic thrill may be present. The murmur of mitral insufficiency is an apical blowing systolic one, lasting throughout systole, and may radiate to the axilla or to the left sternal border. The first heart sound is soft or normal. If there is associated mitral stenosis, the murmur of this lesion will be heard in diastole.

Enlargement of the left ventricle and atrium may be determined roentgenographically. On fluoroscopic examination the left atrium may be seen to pulsate paradoxically during ventricular systole, but this sign is not diagnostic of mitral insufficiency. Calcification of the mitral valve is rarely seen in children. The electrocardiogram may demonstrate left ventricular hypertrophy if the lesion is severe.

A frequent problem is evaluation of an apical systolic murmur without other signs in

patients who have had a mild attack of rheumatic fever or a history of recurrent upper respiratory tract infections. Though many of these patients are considered to have organic mitral insufficiency, the diagnosis is often incorrect. In some the murmur is extracardiac, and sometimes an innocent murmur is transmitted to the apex. Many children with murmurs suggestive of mitral insufficiency lose all evidence of cardiac disease after some years. Wilson observed that only 11 per cent of a group of 179 children with mitral insufficiency retained the signs of this lesion over a period of two to sixteen years. Individual patients may require careful follow-up studies for many years before the cause of the murmur becomes apparent. Untold harm may be done if the patient's activities are reduced only on the basis of the presence of a murmur.

During convalescence children with mild cardiac disease often make great improvement, while those with far advanced cardiac disease suffer from the effects of rapid growth and development. If rheumatic infections recur, the valvular condition becomes progressively worse. For prophylactic therapy, see page 910.

**Mitral stenosis.** Congenital mitral stenosis is described on page 876.

Organic mitral stenosis is nearly always rheumatic in origin and results from sclerosis of the mitral ring and the base of the valve leaflets. It may take two years or more for the lesion to become fully established (Bland, Jones and White). Mitral stenosis is often associated with mitral insufficiency.

In established mitral stenosis the left atrium has difficulty in emptying, which results in hypertrophy and increased pressure in this chamber. The increased pressure is reflected through the pulmonary veins into the pulmonary artery to the right side of the heart, resulting in pulmonary and right ventricular hypertension. The right ventricle hypertrophies, and congestive cardiac failure may be the terminal event. Effort dyspnea due to pulmonary engorgement may be present and is slowly progressive until congestive cardiac failure supervenes. Attacks of paroxysmal dyspnea may occur and are due to left atrial failure. Another symptom is recurrent hemoptysis, probably due to ruptured bronchial veins or pulmonary infarction. Patients with mitral stenosis may have a malar cyanotic tinge. The pulse is small and the jugular venous pressure normal unless congestive cardiac failure or tricuspid insuffi-

ciency has supervened. Varying degrees of cardiac enlargement occur, depending on the associated valvular lesions and rheumatic myocarditis. In severe mitral stenosis without mitral insufficiency the apical impulse is tapping, and an apical diastolic thrill may be palpable. The murmur of mitral stenosis is heard at the apex in mid-diastole or late diastole (presystole). It is low-pitched or rumbling and is often best heard with the patient lying on his left side or after exercise. The first sound is slapping, and the pulmonary second sound is accentuated. An opening snap of the mitral valve may be heard down the left sternal border during diastole. Associated functional pulmonary insufficiency may result in a blowing diastolic murmur down the left sternal border (Graham Steell murmur).

Roentgenologic studies reveal varying degrees of cardiac enlargement, depending on the severity of mitral stenosis and rheumatic myocarditis (Fig. 283). The aorta is small and the pulmonary artery segment prominent. The enlarged left atrium may be visualized in the anteroposterior projection as a prominence below the pulmonary artery and by a double shadow overlapping the right atrium. In the right anterior oblique projection the enlarged left atrium displaces the barium-filled esophagus posteriorly. The left main stem bronchus may be elevated by the enlarged left atrium. The lung fields may occasionally show a fine nodularity, probably due to pulmonary hemosiderosis. Calcification of the mitral valve is not frequent in children.

The electrocardiogram may reveal signs of right ventricular hypertrophy or incomplete right bundle branch block. The P waves are notched and widened and occasionally are tall and spiked. The vital capacity is reduced and the arm-to-tongue circulation time prolonged. Cardiac catheterization is seldom indicated in children with mitral stenosis.

Complications of mitral stenosis include atrial fibrillation, subacute bacterial endocarditis, congestive cardiac failure, functional tricuspid insufficiency and systemic emboli from thrombi in the left atrium.

The *course* and *prognosis* are extremely variable. Some patients succumb during adolescence, and others reach old age. It appears that most patients who die during adolescence have persistent active rheumatic carditis.

*Treatment* is directed toward the prevention of further attacks of rheumatic fever, prophylaxis against the onset of subacute bacterial endocarditis and encouragement to

lead as active and normal a life as possible. Although brilliant results have been obtained by the surgical treatment of mitral stenosis in adults, operation is seldom indicated in children. In rare instances mitral valvotomy can be considered if heart failure persists in the absence of demonstrable active rheumatic carditis.

**Aortic insufficiency.** In the majority of instances aortic insufficiency results from rheumatic heart disease, but occasionally is associated with congenital cardiovascular lesions (see Coarctation of the Aorta and Ventricular Septal Defect). In chronic rheumatic aortic insufficiency, sclerosis of the aortic valves results in distortion and retraction of the cusps. The lesion produces hypertrophy of the left ventricle, which may be extreme. Aortic insufficiency which develops during the acute stage of rheumatic fever is more likely to be permanent than mitral valvular stenosis.

Owing to the reflux of blood through the aortic valve during diastole and to associated vasodilatation, the radial pulses are water-hammer in type, and the carotid arteries show bounding Corrigan pulsations. Associated signs include capillary pulsations in the lips or fingernails, an audible systolic shock over the peripheral arteries (pistol shot) and systolic and diastolic murmurs over the femoral arteries if pressure is applied to the artery just distal to the stethoscope (Duroziez's sign). The systolic blood pressure is elevated, the diastolic lowered.

FIG. 283. Teleroentgenogram of a 9-year-old girl with rheumatic mitral stenosis, tricuspid insufficiency and atrial fibrillation. The gross cardiac enlargement is evident. Pericardial effusion was not found at autopsy.

In severe aortic insufficiency the heart is enlarged with a left ventricular apical heave. Thrills are absent unless there is an associated aortic stenosis. The typical murmur is heard over the pulmonary area with radiation down the left sternal border, to the apex and to the aortic area. It occupies the whole of diastole and is blowing. Associated functional mitral stenosis occasionally produces the typical diastolic murmur of mitral stenosis without organic involvement of this valve (Austin Flint murmur).

*Roentgenologic studies* show prominence and exaggerated pulsations of the left ventricle and aorta. The electrocardiogram may be normal, but in severe cases reveals signs of left ventricular hypertrophy.

The *course and prognosis* depend on the degree of aortic insufficiency (as gauged by the peripheral signs), the size of the left ventricle and the presence or exacerbation of rheumatic infection. *Complications* include the development of congestive cardiac failure, usually preceded by left ventricular failure, and subacute bacterial endocarditis.

*Treatment* consists in prophylaxis against the recurrence of acute rheumatic fever and occurrence of subacute bacterial endocarditis as well as encouragement to lead as active and normal a life as possible.

**Aortic stenosis.** Aortic stenosis in children is usually the result of a congenital lesion (p. 875). Rheumatic aortic stenosis is rare in children, although some degree of stenosis may be associated with aortic insufficiency. The signs of pure aortic stenosis include an anacrotic pulse with small pulse pressure, left ventricular enlargement and a systolic murmur and thrill over the aortic area with radiations to the neck, down the left sternal border and to the apex.

**Tricuspid valvular disease.** Tricuspid involvement is rare. *Tricuspid insufficiency* is usually functional, secondary to right ventricular dilatation. The signs produced by tricuspid insufficiency include prominent pulsations of the jugular veins with a "c" wave, systolic pulsations of the liver and a blowing systolic murmur in the fourth and fifth left parasternal spaces. Atrial fibrillation is frequently present.

*Acquired tricuspid stenosis* is also rare and is usually associated with rheumatic mitral stenosis and sometimes with aortic valvular disease. Tricuspid stenosis produces signs of increased jugular venous pressure with prominence of the "a" wave, presystolic hepatic pulsation and sometimes a rumbling diastolic murmur in the fourth and fifth left parasternal spaces.

**Pulmonary valve disease.** Pulmonary insufficiency is rarely due to organic disease and is usually functional, secondary to congenital lesions such as interatrial septal defects or patent ductus arteriosus. Occasionally it complicates severe mitral stenosis (Graham Steell murmur). The murmurs are similar to those of aortic insufficiency, but the peripheral arterial signs are absent in pulmonary insufficiency. Pulmonary stenosis is usually congenital in origin (see p. 866).

# DISEASES OF THE MYOCARDIUM

## CONDITIONS CAUSING MYOCARDIAL DAMAGE

The status of the myocardium is the factor which influences most the prognosis of cardiac disease. If, in spite of congenital cardiac malformations, acquired valvular disease or arrhythmias, the myocardium is able to provide satisfactory circulation of blood to all tissues, the child will be able to maintain adequate nutrition, growth and normal activities of life. The conditions which may directly affect the myocardium include the following: infections, mesenchymal diseases, endocrine disorders, metabolic and nutritional diseases, neuromuscular diseases, blood diseases, tumors, hypertension and congenital anomalies.

**Bacterial Infections. Diphtheria.** The toxin of diphtheria bacilli may produce peripheral circulatory failure or toxic myocarditis. These complications occur from all types of diphtheria, including the cutaneous form. Peripheral circulatory failure occurs within the first two weeks of the disease and is associated with a rapid thready pulse, cold, pale and clammy skin, and hypotension. In addition to the general therapy for diphtheria (p. 418), these patients are treated with elevation of the foot of the bed and intravenous pressor amines.

Toxic myocarditis occurs during the second and third weeks of the disease. It is characterized by the development of arrhythmia in the form of partial or complete heart block, bundle branch block or extrasystoles. Congestive cardiac failure occurs later and is associated with cardiac enlargement and gallop rhythm. In addition to the arrhythmia, the electrocardiogram shows S-T segment depression and T wave inversion in most leads. The immediate prognosis is grave (about 50 per cent mortality). In the patients that survive, peripheral neuritis is common, but the ultimate prognosis is good. Treatment (see also p. 419) consists in enforcing strict bed rest until all signs of myocarditis have disappeared. Digitalis is reserved for patients with frank congestive heart failure.

**Typhoid fever.** Toxic myocarditis may be inferred if there is electrocardiographic evidence of T wave inversion in most leads. However, this sign may be transient and by itself is of no clinical significance. Cardiac failure is rare, and peripheral circulatory

failure is less common now that specific therapy for typhoid fever is available.

**Acute glomerulonephritis** (p. 1035). Myocardial involvement is considered in patients who have congestive cardiac failure, cardiac enlargement or electrocardiographic abnormalities. Cardiac failure is evidenced by dyspnea and pulmonary congestion, which are soon followed by increased venous pressure and hepatomegaly. Frequently it is difficult to determine whether cardiac failure contributes to edema in acute nephritis. Frank pulmonary edema is not common. Tachycardia, cardiac enlargement, gallop rhythm and a nonspecific apical systolic murmur may be found. Hypertension is usual but not invariable. The electrocardiogram is usually normal, and only a small number of patients show nonspecific T wave inversion or prolonged electrical systole.

In addition to antihypertensive drugs, digitalization is indicated when signs of cardiac failure appear. The response is good, and digitalis may be discontinued after a week or two.

**Other bacterial infections.** Circulatory involvement in bacterial infections is manifest as peripheral circulatory collapse or toxic myocarditis. The incidence of toxic myocarditis is difficult to gauge because it frequently depends on minor pathologic evidence such as cloudy swelling or fatty degeneration. Toxic myocarditis as indicated by tachycardia, gallop rhythm and cardiac enlargement may complicate pneumonia, bacterial endocarditis and septicemia. The prognosis depends on the response of the primary infection to specific antibiotics.

**Viral Infections.** Myocarditis complicating such viral infections as measles, chickenpox and mumps is exceedingly rare. It is difficult to gauge the incidence of myocarditis in *poliomyelitis*; hypertension is not uncommon, but cardiac failure is rare. Terminal pulmonary edema may occur. Nonspecific electrocardiographic abnormalities occur in less than 15 per cent of patients. Recently severe myocarditis has been identified with *Coxsackie B virus* (p. 529).

**Parasitic and Fungal Infections.** Lesions in the myocardium have been described in association with *histoplasmosis*, *coccidioidomycosis*, *toxoplasmosis* and *trichiniasis*. In these conditions the cardiac lesion is usually inci-

dental and seldom produces clinical signs of myocarditis. *Actinomyces* may involve the pericardium and myocardium by direct contiguity as for example from a pulmonary abscess. *Hydatid* cysts of the pericardium may be found on routine roentgenograms of the chest and usually produce symptoms only when they rupture. *Schistosomiasis* may produce pulmonary hypertension and cor pulmonale. *Cruz trypanosomiasis* (Chagas' disease) seldom occurs in the North American continent. The South American literature indicates that this infection may produce acute or subacute myocarditis and sudden death.

**Mesenchymal Diseases.** *Rheumatic carditis* is described on pages 890 and 907.

The cardiovascular manifestations of rheumatoid arthritis, *disseminated lupus erythematosus*, *periarteritis nodosa*, *dermatomyositis* and *scleroderma* are described elsewhere. In *rheumatoid arthritis* pericarditis is not uncommon. In patients with rheumatoid arthritis and mitral or aortic valve disease the latter may be due to coincidental or past rheumatic carditis.

**Endocrine Disorders.** *Hyperthyroidism* produces tachycardia, vasodilatation, wide pulse pressure, cardiac enlargement and rarely atrial fibrillation. *Cretinism* seldom produces gross cardiac involvement, but the electrocardiogram discloses a slower than normal cardiac rate, low voltage of all complexes, but especially the P and T waves, left axis deviation and prolonged electrical systole. Serial tracings indicate improvement of these signs with adequate thyroid therapy and a return to a normal tracing within about one month.

**Metabolic and Nutritional Diseases.** Among vitamin deficiency diseases, *beriberi* (p. 365) causes the most conspicuous cardiac damage. However, in patients with malnutrition the deficiencies are often multiple, including an unbalanced high carbohydrate, low protein diet, and it is difficult to separate the cardiac lesion of one nutritional disease from that of another.

**Neuromuscular Diseases.** In the original description of *Friedreich's ataxia* (p. 1097), heart disease was noted in five of the six cases. In the majority of instances, however, there are few cardiac symptoms, the most common evidence of cardiac involvement being an abnormal electrocardiogram with T wave inversion in the left ventricular surface leads. Arrhythmias may also occur and consist of atrial tachycardia or fibrillation or

extrasystoles. Cardiac failure has been reported.

In *progressive muscular dystrophy* (p. 1271), 50 per cent of children have post-mortem evidence of myocardial involvement similar to that of the striated muscle. Cardiac symptoms, however, are not common in these children, but the electrocardiogram is frequently abnormal and may reveal tachycardia, abnormalities of the P wave, short P-R interval and abnormal Q and T waves. Minimal evidence of right or left ventricular hypertrophy may also occur, and some patients have congestive heart failure.

**Blood Diseases.** In infants and children anemia is the most common blood disease associated with cardiac involvement, as, for example, in leukemia, hemolytic anemias, severe iron deficiency and hemorrhage. Although cardiac output increases when the hemoglobin is below about 7 gm. per 100 ml., cardiac enlargement with or without congestive heart failure occurs only with an extreme reduction in hemoglobin to about 3 or 4 gm. In these patients the heart rate is rapid, the pulse pressure is widened, the venous pressure is increased, and the heart is enlarged. An apical or left sternal border systolic murmur is usual, gallop rhythm is common, and diastolic murmurs in the same areas occur in a few patients. The electrocardiographic changes are such nonspecific ones as depressed S-T segments and flat T waves.

Treatment is directed toward the cause of the anemia. If blood transfusions are indicated in the presence of cardiomegaly or cardiac failure, packed cells are preferred. We have found it useful to measure the venous pressure during the transfusion. This can be accomplished easily by measuring the pressure in the vein being used for the transfusion.

**Tumors of the Heart.** See page 1350.

**Carcinoid** of the small intestine with metastases is associated with a secretion of large amounts of serotonin (5-hydroxytryptamine). In these patients pulmonary and tricuspid valve disease may occur and is associated with patchy areas of reddish-blue cyanosis, attacks of flushing, diarrhea and bronchial asthma.

**Hypertension.** In the majority of instances the etiology of hypertension in children can be clearly ascertained. Renal disease is the most common cause. Coarctation of the aorta has been described elsewhere. Hypertension may be found in patients with poliomyelitis.

lead poisoning, encephalitis and brain tumor. Endocrine disturbances, which may be associated with hypertension, include steroid therapy, pheochromocytoma, congenital adrenal hyperplasia and Cushing's syndrome.

*Essential hypertension* is rare in children. The diagnosis is based on the exclusion of the abnormalities described above.

## CONGENITAL ANOMALIES

### ENDOCARDIAL SCLEROSIS

This condition has been described under a variety of terms, which include fetal endocarditis, endocardial fibrosis, prenatal fibroelastosis and elastic tissue hyperplasia. The term "endocardial sclerosis" is used in this text because it describes the gross appearance of the heart at autopsy and makes no commitment regarding the age at which the disease might originate or its cause.

No single etiologic cause has been established. There is insufficient evidence that the process is the result of inflammation or infection before or after the birth of the child. Other theories of etiology include abnormalities of development of the endocardium or a deficient blood supply to the endocardium and its trabeculae. The disease may occur in siblings.

*Pathologically*, the disease is characterized by a white, opaque fibroelastic thickening of the endocardium, especially of the left side of the heart, which frequently obscures the trabeculation of the inner surfaces of the cardiac chamber. The lesion may spread to involve the valves, especially the aortic and mitral ones. There may be coexisting congenital cardiovascular lesions, which include coarctation of the aorta, patent ductus arteriosus, aortic atresia and premature closure of the foramen ovale. Microscopically, the lesion consists of a fibroelastic thickening of the endocardium which follows the course of the trabecular sinusoids and may result in subendocardial degeneration or necrosis of muscle with vacuolation of muscle fibers. The involved valve leaflets show a myxomatous proliferation with an increase in collagenous elements.

The *clinical picture* is variable, the majority of patients falling into one of the following groups:

1. Young infants, usually less than six months of age, who apparently have been in good health until the sudden onset of congestive cardiac failure; this is frequently pre-

cipitated by a respiratory infection. Death occurs at this early age.

2. Infants with similar symptoms, but of milder degree and with periods of remission. At some time during the first two years of life they may manifest some dyspnea, refusal of feedings, failure to gain weight adequately and recurrent pulmonary infections. There are repeated episodes of congestive cardiac failure, finally ending in death.

3. A miscellaneous group includes patients in whom valvular lesions or associated congenital cardiovascular defects are predominant.

The majority of patients fall into groups 1 and 2. During episodes of congestive cardiac failure the infant is acutely ill with dyspnea, cough and anorexia. Cyanosis is infrequent, but is sometimes found in the terminal phase or as a sign of associated congenital cardiovascular defects. The jugular venous pressure is elevated, the liver greatly enlarged, and edema of the extremities, sacral area or face may be present. Rales and rhonchi in the lung fields are due to intercurrent pulmonary infection and congestion. The heart is moderately or greatly enlarged with a normal or left ventricular apical impulse. Thrills are not common, and murmurs are insignificant. About 25 per cent of patients have a grade I or II blowing systolic murmur down the left sternal border.

Roentgenograms confirm the cardiac enlargement, but the cardiac silhouette is of a nondistinctive contour (Fig. 284). There may be signs of intercurrent pulmonary infection. The electrocardiogram is usually abnormal, but not pathognomonic (Fig. 285).

FIG. 284. Teleroentgenogram of a 7-month-old girl with endocardial sclerosis. The enlarged heart is of an undistinctive contour.

FIG. 285. Electrocardiogram of 3-month-old girl with endocardial sclerosis. Note the abnormal T waves in leads II, aVF and  $V_8$  and the deep Q and tall R waves in aVF and  $V_8$ .

In the majority of cases tall R waves and inversion of the T waves over the left ventricular surface indicate dominance of the left ventricle. These signs are associated with inversion of the T waves in the standard leads and sometimes with a deep S in the right precordial leads. These electrocardiographic changes may also be seen in gargoyism, glycogen storage disease of the heart, aberrant origin of the left coronary artery from the pulmonary artery and medial necrosis or calcinosis of the coronary artery.

More than 90 per cent of patients succumb during the first two years of life; occasional patients survive to adult life. In rare instances symptoms may appear for the first time at five or six years of age.

*Treatment* is directed toward alleviation of congestive cardiac failure and prevention of intercurrent infections.

## OTHER MYOCARDIAL DISEASES

Glycogen storage disease (pp. 268 and 1095) produces myocardial degeneration characterized by deposition of glycogen in the muscle fibers. The hepatic forms of glycogen disease usually do not involve the heart.

Simple hypertrophy of the cardiac muscle has been described in which there is no inflammatory reaction or any extrinsic contributory factors. Damon and Moore have reported an increase in the number and size of muscle fibers, but no changes in the number of nuclei were observed. McMahon, however, has noted mitotic figures in the cardiac muscle fibers of such patients. Some of these cases appear to have a familial basis.

In gargoyism (see p. 1238) the pathologic

FIG. 286. Teleroentgenogram in gargoyism. The enlarged heart shadow is of an undistinctive contour. The ribs are broadened and the intercostal spaces narrowed.

FIG. 287. Electrocardiogram in gargoyism. Note the abnormal T waves in leads I, II, aVF and  $V_6$ . Compare with Figure 285.

lesion in the heart and great vessels is the same as that of the connective tissue found elsewhere in the body. The most pronounced lesions are found in the valves and coronary arteries, but abnormalities in the pericardium and aorta are not uncommon. Significant left ventricular hypertrophy may be present. Many of these patients die of congestive cardiac failure during the second decade. The heart may be moderately enlarged, but murmurs are not diagnostic (Figs. 286, 287).

Calcinosis of the coronary arteries is a rare disease of infancy. Familial incidence has been recorded. The coronary arteries are tortuous and calcareous, and the ventricles, especially the left, are hypertrophied. Other blood vessels may be similarly involved. The onset of cardiac failure is sudden; death usually occurs in infancy.

### TREATMENT OF CARDIAC FAILURE

The underlying cause of cardiac failure must be removed or alleviated if possible. If the cause is a congenital cardiovascular anomaly which is amenable to surgery, medical treatment is indicated prior to the surgical procedure and is continued in the immediate postoperative period. For some diseases, such as hyperthyroidism, hypothyroidism, anemia and beriberi, specific therapeutic measures are available, but in the majority of instances only general procedures are adaptable.

*Bed rest* in a comfortable position is essential. Some patients prefer to lie flat, but for most of them breathing is easier in a semi-reclining position. Initially sedatives or analgesics may be necessary to produce complete relaxation; the most frequently used drugs are morphine, codeine and the barbiturates.

A low *sodium diet* is efficacious in the treatment of cardiac edema and paroxysmal cardiac dyspnea. The oral intake of sodium should be reduced to 0.5 gm. daily; the diet may be made more palatable with a salt substitute. Powdered milk with a low sodium content (Lonalac) is available for infants.

*Oxygen* administered by any method which is effective and comfortable for the patient will help to relieve dyspnea and cyanosis.

*Mercurial diuretics* are the most effective agents for the treatment of cardiac edema and pulmonary congestion due to cardiac failure. Mercaptomerin sodium (Mercuhydrin and Thiomerin) (p. 220) is the most frequently used mercurial, but it should be used cautiously if there is associated nephritis and hematuria. The dose of mercurial diuretics

varies according to the age of the patient and the severity of cardiac failure. In infants 0.25 ml. may be given intramuscularly daily or on alternate days in the early stage of treatment. In older children the dose is 0.5 to 1 ml. The easiest method of gauging the efficacy of the drug is by comparison of daily body weights. When a constant level is reached, it should be maintained. When the acute stage of cardiac failure is over, the injection of a mercurial diuretic is necessary in a few patients once or twice weekly. Mercurials act by increasing sodium excretion; a decrease in venous pressure parallels the diuresis. In adults the action of mercurial diuretics is supplemented with orally administered ammonium chloride, but this is seldom necessary in children. Other diuretics used in conjunction with mercurials include the xanthine derivatives, theobromine and theophylline. Chlorothiazide (Diuril) and acetazolamide (Diamox) are other diuretics which can be used orally (pp. 214, 216). If ascites or pleural effusions produce discomfort, fluid should be removed by paracentesis.

Digitalis should be used in all forms of cardiac failure. The most satisfactory response is obtained in failure due to rheumatic carditis, paroxysmal tachycardia and myocardial diseases. In general, it may be said that patients with primary left ventricular failure respond better than those with primary right-sided failure. Patients with congestive cardiac failure due to cyanotic congenital cardiovascular disease respond poorly to digitalis.

Many preparations of digitalis are available, but familiarity with only a few is necessary. The preparations include those of the whole leaf and purified digitalis glycosides. The ones most frequently used are digitoxin and Digoxin for slow digitalization and maintenance, and lanatoside C (Cedilanid) for rapid digitalization. The dose of digitalis (p. 215) and the rapidity of administration depend on the weight of the patient, the severity of congestive cardiac failure, the type of preparation, and subsequently on the response of the patient.

The average adequate digitalizing dose of *digitoxin* (oral or intramuscular) for children varies from 0.02 to 0.04 mg. per kilogram of body weight, but infants require 0.04 to 0.06 mg. per kilogram. Owing to the wide variations of these dosage schedules, it may be preferable to calculate the digitalizing dose of digitoxin in all age groups on the basis of 0.75 mg. per square meter of body surface (see Nomogram, p. 209). The daily main-

tenance dose of digitoxin is one tenth of the digitalizing dose. The full digitalizing dose is given in divided doses within twelve, twenty-four or forty-eight hours, depending on the severity of congestive failure. If digitalization is required within twelve hours, half of the digitalizing dose may be given immediately and the remaining half in divided doses over twelve hours. The total dose may be more evenly distributed if twenty-four or forty-eight hours are taken for digitalization. Because the size of the effective dose of digitoxin varies greatly in different patients, the dose may need to be modified after part or all of the calculated digitalizing dose has been given. The optimal effect of digitoxin occurs four to eight hours after administration, and its excretion is slow (about ten to fourteen days).

*Digoxin* is more rapidly absorbed and excreted than digitoxin. The optimal effect of Digoxin occurs four hours after administration, and it is excreted within forty-eight to seventy-two hours. The oral digitalizing dose of Digoxin is 0.08 to 0.16 mg. per kilogram of body weight in patients under the age of two years and 0.04 to 0.08 mg. per kilogram in patients over the age of two years. The oral digitalizing dose in all age groups may be calculated on the basis of surface area with a dose of 1.50 mg. per square meter (see Nomogram, p. 209). The digitalizing dose may be given in three or four divided doses over a period of twelve to twenty-four hours, depending on the urgency of therapy. In extremely ill patients one quarter to one half of the digitalizing dose may be given intravenously. The remainder of the digitalizing dose and the daily maintenance dose are given orally. The average daily maintenance dose is 25 per cent of the digitalizing dose.

Lanatoside C (*Cedilanid*) is a glycoside used for rapid intravenous digitalization; it should be reserved for emergency situations. It begins to act within three to fifteen minutes after administration, and optimal effects are achieved in about one hour; it is excreted within twenty-four to thirty-six hours. The digitalizing dose is 0.75 mg. per square meter of surface area (see Nomogram, p. 209). Cautious redigitalization with Digoxin or digitoxin is started about twenty-four to thirty-six hours later.

It cannot be overemphasized that there is a great variation in individual patients to digitalis preparations and that the foregoing dosage schedules are only a guide to therapy for a given patient. The digitalizing dose is effective if the cardiac rate is reduced, the venous pressure and liver size are decreased, dyspnea is relieved and diuresis is instituted. Electrocardiographic evidences of digitalis effect include shortening of electrical systole, depression of the S-T segment with T wave inversion and lengthening of the P-R interval. In many patients the difference between an adequate and toxic dose of digitalis is small. The signs of digitalis toxicity include anorexia, nausea, vomiting, diarrhea, visual symptoms, dizziness, headache and arrhythmias. The arrhythmias consist of atrial and ventricular extrasystoles, paroxysmal atrial tachycardia with block, atrial flutter or fibrillation, bundle branch block, ventricular tachycardia and intra-atrial block. If signs of digitalis toxicity occur, the drug should be discontinued, and potassium chloride may be given orally or by intravenous drip, if the arrhythmia warrants therapy.

The convalescent care of children (p. 231) who have suffered from congestive cardiac failure is important. As the child improves, greater freedom of activity may be permitted, and schoolwork may be resumed. For many months after recovery, rest periods throughout the day and ten to twelve hours' rest at night should be advised.

## DISEASES OF THE PERICARDIUM

Congenital malformations of the pericardium are rare. They consist chiefly of defects of the parietal pericardium and are of little clinical significance.

Pericardial cysts are usually asymptomatic and discovered on roentgenograms of the chest. The cardiopericardial shadow is increased and distorted, depending on the location and size of the cyst. The electrocardiogram is normal. The cysts, which are usually benign, may be removed surgically.

### PERICARDITIS

**Etiology.** The most common causes of pericarditis in children are acute rheumatic fever and bacterial pathogens. Other causes include acute idiopathic or viral pericarditis, rheumatoid arthritis, uremia, tuberculosis, lupus erythematosus, constrictive pericarditis, trauma and postoperative pericarditis.

**Hemodynamics.** The effects on the circulation depend largely on the presence or absence of significant amounts of pericardial fluid, the speed of accumulation of the fluid and the myocardial efficiency. Thus a small amount of fluid in the pericardium with a normal myocardium is compatible with normal cardiovascular dynamics. On the other hand, the rapid accumulation of large amounts of fluid in the pericardium with a normal myocardium may result in cardiac compression or *cardiac tamponade*, as in hemorrhage into the pericardium or in septic pericarditis. Smaller amounts of pericardial fluid with a diseased myocardium may also result in cardiac tamponade as in acute rheumatic fever. Cardiac compression also occurs in long-standing chronic constrictive pericarditis.

The basic physiologic abnormality in cardiac compression is inadequate diastolic filling of the ventricles (Fig. 288), which results in increased pressure in both atria and in the venous systems. The stroke volume is small and more or less fixed. Cardiac output is maintained by tachycardia, and reflex vasoconstriction maintains the blood pressure.

**Clinical Manifestations.** Pain may or may not be present and varies in its intensity, location and distribution. Only the lower third of the pericardium, the area supplied by the phrenic nerve, is sensitive to painful stimuli. Therefore the pain may be referred

to the neck or shoulder. The pain may be precordial and pleural when it is aggravated by inspiration and coughing, and may be referred to the back. Or it may be precordial, constant and uninfluenced by respiration, but aggravated by rotating the trunk or by swallowing (McGuire, Kotte and Helm). The pain is either sharp or a dull, oppressive, poorly localized ache.

The venous pressure varies with the intrapericardial pressure. If the latter is raised, the venous pressure is elevated, especially during inspiration. Hepatomegaly, ascites and edema may also be present. The pulse is normal and small in volume or paradoxical; it depends on the degree of cardiac compression. A small rapid pulse is found in patients with a tense pericardium and a low cardiac output. *Pulsus paradoxus* indicates that the pulse becomes smaller or disappears during inspiration; this sign may be confirmed by measuring the blood pressure during the phases of respiration. In the presence of cardiac compression the precordium is quiet to palpation. A large amount of fluid may be detected by percussion, shifting dullness and by recognizing that the apical impulse is well within the border of cardiac dullness. The heart sounds may be normal or distant. A pericardial friction rub may be audible even in the presence of large amounts of fluid. The rub is heard anywhere over the heart, but is frequently situated over the lower left sternal border. It is superficial, of varying intensity and does not have any definite relationship to the heart sounds.

Pericardial effusion may result in pressure on the left main stem bronchus with collapse of the left lung resulting in percussion dullness and bronchial breathing at the left base (*Ewart's sign*). Similar signs may occur from secondary pleural effusion.

The findings on *roentgen examination* vary according to the amount of pericardial fluid. In dry pericarditis there are no abnormal findings. If the accumulation is large, the cardiopericardial shadow is enlarged, the normal contours are obscured, and the amplitude of cardiac pulsation is decreased. Other non-diagnostic signs include changes in the shape of the cardiac silhouette with changes in posture, divergent vascular shadows at the base, an acute right cardiophrenic angle and rapid changes in the size of the cardioperi-

FIG. 288. Hemodynamics in a patient with cardiac compression. The upper tracing is the electrocardiogram, and the lower is the record of respiration. The middle tracing shows the intracardiac pressures. A, Pulmonary artery; B, right ventricle; C, right atrium. Note the diastolic dip in the right ventricular curve and the high right atrial pressure (see text).

cardial shadow. The radiologic findings are not pathognomonic and may be simulated closely by acute cardiac dilatation. Pericardial calcification due to chronic constrictive pericarditis is rare in children.

The *electrocardiogram* is abnormal in many instances. The abnormalities are widespread and involve most of the leads. In the acute phase the S-T segment is elevated, and the QRS voltage may be low. As healing progresses the S-T segment becomes isoelectric or depressed, and the T waves are flattened, diphasic or inverted. The graph returns to normal when the pericarditis heals, although T wave inversion may persist for many months after clinical recovery. This electrocardiographic pattern may be transient and localized, and may be recognized only with serial tracings.

In the presence of cardiac compression *cardiac catheterization* reveals an increased pulmonary "capillary" and right atrial pressure. The pulmonary artery and right ventricular pressures are normal or moderately elevated, and there is a conspicuous dip in early diastole in the right ventricular pressure curve (Fig. 288). If the catheter is coiled in the right atrium, the width of the pericardial shadow can be detected. The diagnosis may be confirmed also by angiocardigraphy, which delineates the cardiac chambers and separates that part of the cardiac silhouette which is produced by pericardial effusion.

*Cardiac tamponade*, whatever the etiology, is a medical emergency. If the cardiac output is not maintained during cardiac compression,

the patient goes into shock. The intrapericardial pressure must be reduced immediately, usually by pericardiocentesis.

**Rheumatic Pericarditis.** Rheumatic pericarditis is usually fibrinous or serofibrinous, and a large accumulation of fluid is unusual. Its diagnosis proves the presence of active rheumatic carditis. These patients are usually acutely ill with fever, dyspnea and pericardial pain. The heart is frequently enlarged, and a pericardial friction rub is common. The electrocardiographic changes are as described above. Treatment is directed towards the rheumatic illness as a whole, the relief of pain and pericardiocentesis in the rare cases with cardiac tamponade. Rheumatic pericarditis, per se, does not produce serious after-effects and does not lead to constrictive pericarditis. Children with rheumatic pericarditis usually have more serious underlying carditis and therefore a poorer long-term prognosis.

The differential diagnosis of rheumatic pericardial effusion from acute cardiac dilatation may be difficult. In some patients it may be necessary to resort to pericardiocentesis to establish the presence or absence of significant amounts of pericardial fluid. The essential difference between dry rheumatic pericarditis and other forms of dry pericarditis such as acute benign pericarditis is the presence in the former of significant systolic and/or diastolic murmurs as well as other stigmata of acute rheumatic fever.

**Septic Pericarditis.** Septic pericarditis is produced by a variety of organisms, including

pneumococci, streptococci and staphylococci. Foci of infection, usually pneumonia, are frequently present at other sites. The purulent exudate in the pericardium is of varying consistency, and coagulated masses of fibrin and pus are common.

The patients are acutely ill with fever, pericardial pain and tachypnea. The heart is enlarged, murmurs are insignificant, and a friction rub may or may not be present. The electrocardiographic and radiologic pictures are as described above. The diagnosis is confirmed by pericardiocentesis. In some patients this procedure may yield only small amounts of pus, owing to the consistency of the exudate and the multiple loculations. Surgical drainage is usually necessary and should be instituted early. This therapy with the use of appropriate antibiotics gives excellent results, and the long-term prognosis appears to be good.

**Acute Benign Pericarditis (Idiopathic, Nonspecific or Viral).** This disease frequently follows an upper respiratory tract infection with an average latent period of twelve days (McGuire, Kotte and Helm). The onset is usually acute with fever, and pericardial pain and a friction rub are common. Varying amounts of straw-colored pericardial fluid develop, but cardiac compression is rare. The electrocardiogram usually shows the typical pattern of pericarditis.

Although the disease is benign without any after-effects, recurrences, sometimes multiple, have been noted in up to 20 per cent of patients. Symptomatic treatment is all that is usually necessary. Corticosteroid therapy may be considered in the severe forms of the disease or in patients with multiple recurrences.

**Pericarditis in Rheumatoid Arthritis.** Pericarditis may occur at any stage of rheumatoid arthritis and may precede the typical joint manifestations. Pericardial effusion is rare and a pericardial friction rub common. Steroid therapy is indicated in the severe forms of the disease.

**Pericarditis in Uremia.** In the terminal stages of uremia a pericardial friction rub may be heard. The pericarditis seldom produces symptoms, and the electrocardiographic changes are minimal.

**Tuberculous Pericarditis.** Tuberculous pericarditis is usually secondary to a lesion in the hilar nodes or in the lung. Pericardial effusion is common and is later followed by a fibrotic reaction which may result in constrictive pericarditis. The onset may be in-

FIG. 289. Purulent pericarditis due to type 29 *Pneumococcus* in an infant aged 12 months.

sidious and be associated with cough, dyspnea, fever, weight loss and night sweats. The diagnosis depends on signs of tuberculosis elsewhere in the body and recovery of the organism from the sputum, gastric washings or the pericardial fluid. Treatment is that of the tuberculous infection (p. 464).

**Chronic Constrictive Pericarditis.** This disease is rare in children. In the majority of instances the etiology is unknown, or the disease may follow tuberculosis and possibly septic pericarditis. The hemodynamics and clinical picture are those of chronic cardiac compression and must be distinguished from chronic congestive heart failure. Atrial fibrillation may occur. If the constriction is severe, pericardiectomy is advised.

**Postoperative Pericarditis.** Postoperative pericarditis may follow any direct surgical procedure in the heart. Friction rubs are common during the first two weeks after surgery. In some patients signs of pericarditis without significant effusion recur some weeks after surgery and may be repeated over a period of about three to four months. The prognosis is good, and treatment is symptomatic.

## DISEASES OF THE BLOOD VESSELS

*Congenital anomalies* involving the structure, origin or position of blood vessels may occur in any part of the body, but rarely do they cause any circulatory disturbance unless the aorta and its primary thoracic branches, the pulmonary artery or coronary arteries, are involved (See *Congenital Heart Disease and Diseases of the Myocardium*). *Fetal blood vessels*, especially the umbilical vein and hypogastric arteries, may be the site of infection in the neonatal period. *Hemangiomas* are described on page 1358. *Dilatation of veins* (varices) rarely occurs in childhood as a congenital malformation, but may result from obstructive lesions such as tumors, thromboses and hepatic cirrhosis.

### ANEURYSMS AND FISTULAS

Aneurysms are not common in children and occur most frequently in the aorta in association with coarctation of the aorta, patent ductus arteriosus and Marfan's syndrome and in intracranial vessels (p. 1080). They may also occur secondary to an infected embolus, infection contiguous to a blood vessel, trauma, congenital abnormalities of structure, especially of the medial coat, and arteritis, e.g., periarteritis nodosa.

*Arteriovenous fistulas* may be limited to small cavernous hemangiomas or may be extensive. In a group of forty-four children observed by Ward and Horton, congenital arteriovenous fistulas involved the vessels of the lower extremity in twenty-five instances, the upper extremity in nine instances, the brain in four, the face, scalp and neck in four, and produced hemihypertrophy in two instances. *Trauma* accounts for a large number of arteriovenous fistulas.

The *clinical manifestations* of arteriovenous fistulas appear to depend primarily on the size of the shunt across the fistula and the associated vasodilatation. Discoloration of the skin, prominence of the superficial vessels and local edema may occur at the site of the fistula or involve a whole extremity. Prominent arterial pulsations and a continuous machinery bruit may be heard over the site of the lesion, especially in the traumatic types.

The venous pressure is elevated in an affected extremity, the temperature of the skin may be higher at the site of the lesion, and the venous oxygen saturation distal to the fistula is higher than that of venous blood taken from a similar site on the unaffected side. In extensive fistulas there is left ventricular hypertrophy and dilatation, a widened pulse pressure and congestive heart failure. Arteriograms with the injection of contrast material into an artery proximal to the fistula confirm the diagnosis. Symptomatic arteriovenous fistulas should be eradicated surgically.

### FROSTBITE

Frostbite may occur in the face or extremities from prolonged exposure to cold. The skin first becomes red and then pale or rarely cyanotic, as the arterioles remain in a spastic condition in an effort to preserve the body heat. During thawing, hyperemia occurs, and blisters may form on the skin. Gangrene may occur if early relief is not obtained.

The *treatment* consists in application of mild heat and gentle massage, but vigorous rubbing should be avoided to prevent irritation of the skin. Overheating the affected tissue before the blood supply is re-established may lead to edema and gangrene.

### EMBOLISM

Emboli, consisting of bacteria and fibrinous material, usually arise from mural thrombi or vegetations in the heart or large blood vessels, as for example in subacute bacterial endocarditis. Other rarer causes of emboli include fat (secondary to trauma) and foreign material, such as air, introduced accidentally into the vascular system during therapeutic procedures. In patients with atrial or ventricular septal defects, emboli arising in the systemic venous system may pass across the defect and enter the systemic arterial system (*paradoxical embolus*).

When emboli lodge in an artery, the blood flow through the vessel is compromised. If the collateral circulation to the involved area is inadequate, necrosis or gangrene supervenes. However, if the collateral circula-

tion is adequate, the emboli may be silent; thus an embolus to the arteries of the forearm may not give rise to any symptoms and is detected only when the radial or ulnar pulse disappears.

The symptoms and signs produced by arterial emboli depend on their location; e.g., an embolus to the middle cerebral artery may result in hemiparesis; an embolus to the femoral artery may result in ischemia with or without gangrene in the lower extremity. If the emboli are infected, an abscess forms locally.

*Treatment* of arterial embolism consists in eradication of the source of embolism, as for example treatment of subacute bacterial endocarditis and therapy to increase the collateral circulation to the affected area. Surgical therapy such as embolectomy, sympathectomy and amputation may be indicated in specific instances.

Pulmonary embolism is not as frequent in children as in adults. Thrombosis of the calf veins with secondary pulmonary embolism is rare in children. However, pulmonary emboli may arise secondary to subacute bacterial endocarditis in patients with a left-to-right shunt. Occasionally pulmonary embolism is seen in older children with chronic rheumatic heart disease and atrial fibrillation. Multiple small pulmonary emboli have been described elsewhere (see Primary Pulmonary Hypertension, p. 879).

## THROMBOSIS

The common cause of *arterial thrombosis* in

children is polycythemia secondary to severe cyanotic congenital heart disease. A frequent site for such thrombi is in the brain, but they may occur anywhere in the body. They may be precipitated by dehydration.

*Venous thrombosis* may occur in veins used for prolonged intravenous therapy or in an area surrounding an infective process. The inflammation in the vein (*phlebitis*) is usually local, and the thrombi seldom give rise to emboli.

Venous thrombosis may also occur in patients with severe cyanotic congenital heart disease and polycythemia. A common site for these thrombi is in the venous sinuses of the brain, and they too may be precipitated by dehydration.

Any severe illness associated with intense dehydration may be complicated by venous thrombosis. This complication is more frequent in infants with diarrhea or septicemia. The common site for thrombosis is in the sagittal sinus of the brain and in the renal vein with extension into the inferior vena cava. (See Vascular Disorders of the Central Nervous System, p. 1080, and Hemorrhagic Infarction of the Kidney, p. 1053.)

## RHEUMATIC FEVER

Rheumatic fever is one of the leading causes of chronic illness, invalidism and death in children. Although the onset usually is during childhood, the effects are projected into adult life. During World War II 100,000 young men were ineligible for military service because of rheumatic heart disease, and an additional 40,000 had an initial attack or a recurrence of the disease.

The mortality rate due to rheumatic heart disease appears to be declining from both the initial attack and from recurrences. Whether this apparent decline is due to changes in the natural history of the disease, to the improvement in the economic condition of urban populations or to more effective control of streptococcal upper respiratory tract

infections is not known. If the prophylactic procedures for decreasing the incidence of initial attacks and recurrences recommended by the American Heart Association come into general use, the morbidity and mortality caused by rheumatic fever may be still further reduced.

In 1888 Cheadle pointed out that polyarthritis, chorea and heart disease formed part of the same clinical syndrome. Rheumatic fever is now recognized as a general systemic disease characterized by frequent recurrences or exacerbations. It may occur at any age, but usually begins in childhood. The symptoms and course are extremely variable, and the diagnosis is often difficult. Three major clinical manifestations, however,

are pathognomonic: migratory polyarthritis, Sydenham's chorea and carditis. Subcutaneous nodules, although they occur frequently in the course of rheumatic infection and are a characteristic manifestation, are also found in rheumatoid arthritis.

**Etiology.** Both initial and subsequent attacks of rheumatic fever follow scarlet fever or upper respiratory tract infections due to group A beta hemolytic streptococci. Attacks of rheumatic fever also occasionally follow streptococcal skin infections. However, unless the presence of streptococci in the pharynx of such patients is excluded by throat cultures, it seems possible that the skin lesions may have been preceded or accompanied by an inapparent streptococcal upper respiratory tract infection. The common cold, influenza and the contagious diseases of childhood, with the exception of scarlet fever, do not precipitate rheumatic attacks. Further evidence that infection with group A hemolytic streptococci bears a specific relation to the development of rheumatic fever has been obtained by prophylactic administration of sulfonamides or penicillin. If streptococcal pharyngitis is prevented by this means, rheumatic subjects escape rheumatic recurrences. At present, however, it is not known whether streptococci act in conjunction with some other agent or are the sole cause of rheumatic fever, and, if so, by what mechanism they produce the disease.

The development of relapses in rheumatic patients after streptococcal infections usually follows a characteristic pattern. The attack of streptococcal pharyngitis may be extremely mild or moderately severe and has been designated by Coburn as phase I. In most instances the symptoms of the respiratory infection subside quickly and are followed by a latent or nonsymptomatic period (phase II), usually lasting one to three weeks, which in turn is followed by the onset of acute rheumatic fever (phase III).

After outbreaks of pharyngitis or scarlet fever, often caused by a capsulated strain of a single type of group A hemolytic streptococci, the percentage of rheumatic children who have rheumatic sequels varies greatly. A child who escapes a rheumatic recurrence after one streptococcal infection may subsequently have a recurrence after another infection. The upper respiratory tract infection may be caused by any of the forty or more specific types. The regular occurrence of a latent period (phase II) and the inability to demonstrate streptococci in the affected tis-

ues or in the blood during an acute attack (phase III) suggests that hypersensitivity to these microorganisms or their products may be the cause of rheumatic fever. The similarity of the symptoms of serum sickness, namely, polyarthritis, skin manifestations, leukocytosis and fever, to those of rheumatic fever lends support to this view. Further studies may show that the characteristic lesions of rheumatic fever are due to enzymatic action on connective tissue either by streptococcal enzymes themselves or by the catalytic effect of some streptococcal derivative on enzymes already present in the body. Another possibility is that the streptococcal pharyngitis facilitates invasion by an unknown filtrable agent. So far, attempts to demonstrate a virus have been unsuccessful, as have attempts to transmit rheumatic fever to animals.

**Epidemiology.** The incidence of rheumatic fever in the United States is not accurately known, because it is not a reportable disease in most communities and, in its milder forms, is frequently overlooked. It is estimated that about 1,000,000 people in the United States have rheumatic fever.

**Climate.** Rheumatic fever is most prevalent in the temperate zones, although it is more common in subtropical and tropical climates than was formerly supposed. The incidence of rheumatic heart disease in adults who have lived all their lives in the South apparently is almost as high as in the North, suggesting that the onset in southern latitudes may be more insidious. Climate appears to be a more important factor than racial susceptibility; whereas rheumatic fever is relatively uncommon in Puerto Rico and southern Italy, Puerto Rican and Italian children often contract the disease shortly after their arrival in the northern part of the United States.

**Season.** There is a definite seasonal incidence of rheumatic fever which varies in different localities. On the west coast of the United States the peak is usually reached in January and February, along the Eastern seaboard in March and April and in England, in November. In general, the seasonal variation in rheumatic fever follows the curve and incidence of streptococcal diseases.

**Race.** There are no data which permit valid conclusions as to differences in racial susceptibility.

**Sex.** Although it is frequently stated that rheumatic fever is more common among girls than boys, available data do not show a distinct difference in this respect.

**Age at onset.** Rheumatic fever is rare in children under three years of age. The age of greatest incidence is between five and fifteen years. First attacks occur most commonly from six to eight years of age.

**Socio-economic factors.** Rheumatic fever is usually considered to be a disease of the poor, since it is relatively uncommon among children from wealthy or middle class homes. It is also essentially an urban disease. Attempts to relate the high incidence to nutritional factors have so far failed. The prevalence of rheumatic fever among Army and Navy recruits during World War II suggests that infection through close contact of susceptible persons rather than a deficient diet may explain the high incidence of this disease.

**Familial incidence.** Rheumatic fever frequently occurs in more than one member of a family. Studies have shown that a higher percentage of children born of rheumatic parents contracted the disease than of those born of nonrheumatic parents and that the incidence was higher in relatives of rheumatic children who lived in separate households than among relatives of a control group of nonrheumatic children. Further work indicates that the risk of contracting the disease in a rheumatic family is greatly increased by association with another member of the family suffering from an acute attack. These data suggest that the tendency to acquire rheumatic fever may be inherited, but that contact with the etiologic agent is necessary.

**Pathology.** The characteristic lesions of rheumatic fever are found in the connective tissue of the heart, in the arteries and in the subcutaneous tissue. Collagenous structures become edematous, often resulting in the formation of a granuloma. This granuloma, observed by Aschoff in 1904 and known as the Aschoff body, constitutes the pathognomonic histologic lesion of rheumatic fever. Typical Aschoff bodies are usually most numerous in the interventricular septum and in the wall of the left ventricle, but they are also often demonstrable in the left auricular appendage obtained by biopsy during commissurotomy. The cellular reactions in the valves and in the subcutaneous tissue (subcutaneous nodules) resemble those found in the myocardium.

Depending on the location of the lesions, exudative and proliferative or predominantly exudative manifestations develop. Effusions into the joint cavities, the pleura or the pericardium are examples of the primarily exuda-

tive type of response; the lesions in the myocardium, the valves and the subcutaneous tissues are both exudative and proliferative. Transient rheumatic effusions are absorbed without causing permanent injury, but proliferative reactions often follow repeated or long-standing exudates, leading to formation of extensive adhesions, especially in the pericardium.

Large pericardial effusions are relatively uncommon, but evidence of pericarditis is found in most children dying of acute carditis. Both the parietal and the visceral layers are affected. The serous surfaces are red and roughened, and fibrin is deposited. The pericardial fluid may be slightly increased and is sometimes turbid, but never purulent. Cicatrization causes localized thickening of the epicardial surface, and in severe cases the epicardial and parietal layers may become adherent.

MacCallum described a characteristic rheumatic lesion in the endocardium of the left atrium which is often visible grossly as a thickened, opaque and roughened patch. Acute valvular lesions appear as warty vegetations or verrucae along the line of closure. Microscopically, the verrucae consist of hyaline masses. Inflammatory cells are present in the entire valve leaflet and in the chordae tendineae. The formation of scars, as the lesions heal, results in thickening of the leaflet and shortening of the chordae tendineae. Valvular sclerosis develops slowly, usually requiring months or years. Valvular deformities in most instances are due to repeated insults.

Functional impairment of the heart is the result of damage to one or more of its component structures: the myocardium, the endocardium, including the valves, or the pericardium. The extent of the damage determines the degree of impairment.

Since patients with active chorea rarely die, few pathologic studies of the central nervous system in this disease have been made. The findings reported are not consistent, and no characteristic lesions have been described.

**Clinical Pattern.** The latent (incubation) period (see p. 904) usually varies from one to three weeks. The clinical course of rheumatic fever varies greatly. The onset may be acute or insidious, the initial attack at times not being recognized. It is not uncommon to discover unsuspected cases of rheumatic heart disease in routine examinations of children. Either no history of previous rheumatic

attacks is obtained, or there is only a history of equivocal symptoms such as "growing pains," fatigability, nosebleeds, pallor, attacks of abdominal pain or frequent colds.

In the majority of instances, however, typical attacks of any of the three major rheumatic manifestations, polyarthritis, chorea and carditis, tend to recur at varying intervals of time. Most attacks are monocyclic, lasting one to three months. In some children, however, the signs of rheumatic activity continue much longer with intermittent exacerbations. A polycyclic attack of this kind should be differentiated from a true recurrence. A recurrence is a new attack following a streptococcal upper respiratory tract infection in a rheumatic subject in whom there has been no clinical or laboratory evidence of rheumatic activity for at least three months. Recurrences are most common during the first and second years after the initial attack. If a child after apparent recovery from an initial attack remains free of rheumatic manifestations for five years, the prognosis is usually good. Except in the case of chorea, careful questioning will usually reveal a history of a respiratory infection or an attack of scarlet fever preceding the initial attack or the subsequent relapses. The tendency to rheumatic recurrences is greatest during childhood and declines after puberty.

In children less than six years of age carditis is often the presenting symptom, whereas in older children polyarthritis and chorea are more common. Signs of carditis in most instances appear only during subsequent attacks.

**Major Rheumatic Manifestations. Arthritis.** Usually the larger joints (ankles, knees, hips, wrists, elbows, shoulders) are involved, often in succession. Rarely, only one joint is affected. The duration of involvement of each joint is variable and may last only a day or two. The joint is usually swollen and tender to touch and may be hot and red. Active and passive motion is painful. Occasionally the small joints of the fingers and toes are involved. In contrast to rheumatoid arthritis, permanent deformities are never caused by rheumatic polyarthritis. The temperature is usually elevated to 101° or 102° F., a moderate leukocytosis is present, and the erythrocyte sedimentation rate is increased.

Patients with polyarthritis may have cardiac involvement even if definite clinical evidence of carditis is lacking. It is therefore advisable to secure several electrocardiograms during the course of polyarthritis. The most

frequent finding is a prolongation of the conduction time. Only increases of at least 0.04 second in tracings with comparable rates are significant. Usually the P-R interval returns to its previous length, but sometimes it remains permanently prolonged. Other indications of myocardial involvement are inversion of the T waves in any two of the three standard leads, and various types of arrhythmias. Such changes are transitory, but provide objective evidence of carditis. In some instances, a comparison of teleroentgenograms taken at the beginning of the attack and after recovery may show a transient increase in the size of the heart.

**Chorea (Sydenham's chorea, St. Vitus' dance).** Chorea is a disorder of the central nervous system characterized by emotional instability, purposeless movements and muscular weakness. The attacks are recurrent and often prolonged, but eventually recovery is complete. Chorea occurs most commonly between the ages of seven and fourteen years, with the peak incidence at eight years. It is rare after puberty and never occurs after the age of twenty years.

The onset is almost always gradual. The mother states that the child, previously well controlled, has become increasingly nervous. He tends to drop things and stumbles frequently. Often the school teacher reports grimacing and writing difficulties. Speech becomes indistinct, and characteristic purposeless movements of the arms and the legs develop. The movements are increased by effort, excitement and fatigue, but cease when the patient is asleep. Muscular weakness is frequent, so that the child is unable to walk, talk or even sit up. Often the movements are so violent that the patient has to be placed in a padded crib to prevent injury. Infrequently only one side of the body is involved. Symptoms of chorea do not occur concurrently with active arthritis.

The relation of chorea to rheumatic fever has been questioned, chiefly because evidence of general infection is lacking and the incidence of associated carditis is low. Choreic patients are usually afebrile, and the cerebrospinal fluid shows no abnormalities. The C-reactive protein is negative, and the leukocyte count, sedimentation rate and the antistreptolysin-O titer in many instances are normal. It has been suggested that the absence of serologic evidence of a preceding streptococcal infection may be due to a long latent period between the attack of pharyngitis and the appearance of chorea.

Certain clinical tests may aid in establishing the diagnosis of chorea. In mild cases the choreiform movements are exaggerated after periods of direct questioning or enforced quiet. Dysfunction of speech may be elicited by having the child count rapidly to ten and then back to one; for the first few numbers he may speak clearly, and then suddenly the speech becomes thick, or he hesitates or is unable to utter a sound for several seconds. When he talks, there may be a clucking sound, due to the sudden contraction of the tongue to the floor of the mouth. There is only slight resistance to passive movements. The hand grasp is frequently weak and may consist of spasmodic contractions followed by rapid relaxation. Fibrillary twitchings in the muscles may also be detected while the hand is held. There may be a broad grin one moment, followed suddenly by a "poker-face" or even a tearful expression. When the tongue is protruded, it is impossible to hold it quietly, and its undulating, jerky movements have been described as a bag of worms. The child may bite the tongue to keep it protruded, or may jerk it back rapidly. If he is asked to extend his arms with outstretched fingers in front of him, he soon hyperextends his wrists and his fingers; or if he is asked to raise his arms above his head, he soon turns his arms so that the backs of the hands oppose. With deep breathing the diaphragm may be drawn upward so that the abdominal wall is drawn inward. The response to the patellar reflex is often "hung-up."

**Carditis** (see p. 890). Carditis is the most serious manifestation, since it often leads to permanent disability or death. In most cases of acute carditis the temperature is elevated and may be as high as 104° F. Leukocytosis is present. The hemoglobin often falls rapidly, and pallor is striking. The pulse is of poor quality, and tachycardia is out of proportion to the fever. The respiratory rate is increased. Weakness, prostration, orthopnea, cyanosis and precordial pain are frequent symptoms in severe cases. Evidence of cardiac decompensation may develop. Cardiac dilatation occurs in most cases and is probably due to the weakening of the muscle fibers as a result of the inflammatory reaction. The apical impulse becomes wavy, and the heart sounds are muffled. Owing to exaggeration of the third heart sound, gallop rhythm is frequent. Often the muscular quality of the first heart sound is diminished, resulting in a "tick-tock" rhythm. New murmurs arise,

or the quality of murmurs previously present may change and assume a musical or "seagull" quality. Prolongation of the conduction time and arrhythmias resulting from dropped beats to 2:1 or complete heart block occur occasionally. (See page 886 for other electrocardiographic changes.) Atrial fibrillation is uncommon in children and develops only in patients with long-standing heart disease.

**Pericarditis** (see p. 899). Precordial pain usually indicates pericarditis; a friction rub, a leathery or scratchy to-and-fro sound, is pathognomonic. It may be heard over the entire precordium or only in limited areas. Most pericardial effusions are not massive, but occasionally are sufficiently extensive to cause respiratory embarrassment. In most instances the symptoms subside without paracentesis. The differentiation of cardiac dilatation and pericardial effusion is difficult by physical examination and by roentgenography. In pericardial effusion the apical impulse may disappear, the heart sounds are distant, but the quality of the pulse remains fair. The cardiac silhouette on the roentgenogram is usually more rounded with an effusion than with dilatation.

**Subcutaneous nodules.** Nodules are one of the most characteristic manifestations of rheumatic fever and are not observed in any other disease except rheumatoid arthritis. They are found on the extensor tendons of the hands and feet, on the elbows (Fig. 290), at the margin of the patella, on the scalp, over the scapula and over the spinous processes of the vertebrae. They vary from 0.2 to 2 cm. in diameter. They are often more readily felt than seen and can easily be

FIG. 290. Rheumatic nodules at the elbow in a Negro girl 10 years of age. She had polyarthritis and endocarditis; later, pericarditis developed. She died 3 weeks after the picture was taken.

FIG. 291. Annular erythema on the chest and abdomen of a boy 8 years of age, who also had rheumatic carditis.

overlooked unless a careful search is made. They tend to be distributed symmetrically. They lie in the deep connective tissue, and the skin is freely movable over them. Nodules are never painful. They are most numerous in children with severe rheumatic infections and with extensive cardiac involvement.

**Symptoms Frequently Associated with Rheumatic Fever, but not Pathognomonic.** *Muscle and joint pains.* Children frequently complain of vague muscle and joint pains commonly known as "growing pains." In most instances they are confined to the lower extremities, and it is important to exclude orthopedic defects. Such pains which occur only at night are rarely rheumatic, nor are most other muscle and joint pains, but periodic examinations are indicated.

*Abdominal pain.* Abdominal pains occur frequently during the course of acute rheumatic attacks and may simulate appendicitis. Pain of rheumatic origin is often localized in the epigastrium, and muscular rigidity is absent. In some instances, however, acute appendicitis cannot be excluded, and laparotomy is indicated. There are usually no abnormal findings, although occasionally the mesenteric lymph nodes are enlarged and congested and petechial hemorrhages are found in the mesentery. If there are other definite signs of rheumatic fever and if the

patient is under close observation, operation can usually be delayed temporarily and often becomes unnecessary.

*Epistaxis.* Nosebleeds are common in rheumatic children and are often an early manifestation. They may be of such severity that transfusion becomes necessary. Usually no lesion of the nasal mucosa is found. Hemorrhagic manifestations such as epistaxis, purpura and occasionally hematuria in rheumatic subjects are not associated with thrombocytopenia. The nature of the underlying vascular lesions is not known.

*Skin manifestations.* Various types of erythema occur, usually erythema marginatum (erythema annulare) (Fig. 291), less often erythema multiforme. The lesions come and go for months or years. Whether rashes of this kind, unless accompanied by other evidence, should be considered a sign of rheumatic activity is controversial. Purpuric eruptions (nonthrombocytopenic) are relatively uncommon.

Erythema nodosum occurs occasionally as it does in a variety of other conditions, including tuberculosis and coccidioidomycosis.

*Low grade fever.* In some instances there may be no abnormal manifestations other than a low grade fever during the late afternoon. If other cause for the fever is not established, the possibility of rheumatic fever must be kept in mind. An erythrocyte sedimentation rate is indicated in all such instances and should be repeated at intervals of three to four weeks. When there are equivocal cardiac changes, the diagnosis of rheumatic fever becomes more probable.

*Pneumonic consolidation and pleurisy.* Occasionally so-called rheumatic pneumonia or pleurisy develops during the course of acute carditis. Signs of consolidation appear first in one part of the lung and then in another, and may occur in the absence of congestive failure.

There is doubt whether the pulmonary involvement represents a rheumatic infection of the lung itself, or is the result of generalized vascular changes involving the lungs as well as other organs. Since Aschoff bodies are never found in the lung, the latter theory seems more likely. According to Epstein and Greenspan, the pathologic findings can be explained on the basis of increased capillary permeability, and consist in alveolitis resulting from diapedesis of erythrocytes and transudation of sero-albuminous material.

*General symptoms.* Since rheumatic fever is a generalized disease it often produces such

general symptoms as pallor, fatigue, anorexia and loss of weight. In such instances, when a definite diagnosis cannot be established, the patient should be examined at frequent intervals, especially after upper respiratory tract infections.

**Differential Diagnosis.** Rheumatic polyarthritis may be confused with *rheumatoid arthritis* in its early stages. The chronicity of the latter disease, however, soon becomes apparent. The response of rheumatic polyarthritis to salicylates is so rapid and striking that administration of these drugs may be used as a therapeutic test to differentiate the two. In *septic arthritis* usually only one joint is involved and the patient has more toxic symptoms. The fluid aspirated from a rheumatic joint is clear or only slightly turbid, whereas that obtained in pyogenic infections is frankly purulent except in the earliest stage, when the presence of bacteria is a distinguishing factor.

*Syphilitic hydrarthrosis* can be distinguished from rheumatic polyarthritis by its chronicity, the presence of other physical signs of syphilis and serologic tests. Joint pains may occur in *acute leukemia*, which can be identified by blood studies. The generalized hyperesthesia common in the early stages of *anterior poliomyelitis* may suggest rheumatic fever. Poliomyelitis is rare in the early spring months, when rheumatic fever is prevalent, and nuchal rigidity is common and the pain is not localized in the joints. The rarity of rheumatic fever in the first two or three years of life should be borne in mind in the differentiation of *acute* or *chronic arthritic symptoms in infants*.

Cardiac enlargement and dilatation of the mitral ring, which occur frequently in severe *anemias*, often suggest mitral insufficiency of rheumatic origin. This is particularly true of Negro patients with sickle cell anemia.

Any disease which causes symptoms of *low grade infection*, such as tuberculosis, undulant fever and sinusitis, can simulate rheumatic fever and must be excluded. In all cases of unexplained fever, patients should be examined during the febrile episode and again several weeks later.

At the onset of *chorea* there may be some difficulty in differentiating the grimacing of chorea from habit spasm. In the latter condition the same movements are repeated, whereas the facial twitchings in chorea are variable. *Athetoid movements* are slower, usually limited to the extremities, most often to the hands. In *encephalitis, tuberculous menin-*

*gitis* and *brain tumor* the choreiform movements are, as a rule, more or less stereotyped, and the history and other physical signs help in the differentiation. *Maladjustments* at home or elsewhere may produce nervous manifestations and instability. Emotional instability is not uncommon in *mentally retarded children*. *Hyperthyroidism* must also be considered when nervousness is the most prominent symptom. The peculiar and purposeless movements of the arms and legs in chorea are characteristic, however, and the diagnosis usually offers no difficulty. It should be recognized that a child in close contact with a case of active chorea may imitate choreiform movements without having the disease.

**Evaluation of Clinical Status.** When a diagnosis of rheumatic fever is established, it is important to decide whether the rheumatic process is active or quiescent.

**Clinical appraisal.** Salicylate therapy may and often does mask the symptoms of rheumatic fever; therefore it should have been discontinued for at least fourteen days before it is concluded that there is no fever or joint involvement. Low grade fever is often an indication of continued rheumatic activity. Rectal temperatures should be taken in the morning and at bedtime, and the child should have been at rest for at least a half-hour, since exercise or excitement may elevate the temperature normally. The presence of subcutaneous nodules indicates active rheumatic infection. Whether recurring erythematous rashes by themselves have the same significance seems doubtful. Since the pulse rate of children is often labile and likely to be accelerated by emotional factors, the presence of tachycardia should be determined during sleep. Persistent tachycardia in the absence of fever is evidence of active cardiac involvement. Extension of endocardial involvement from the mitral to the aortic valve is also indicative of rheumatic activity.

The child should be kept in bed until the pulse rate is normal, and the C-reactive protein is negative and the erythrocyte sedimentation rate decreasing. If the rheumatic process has become quiescent, the heart sounds should have improved in quality, and any abnormalities of cardiac rhythm should have disappeared. If cardiac enlargement has been present, a decrease in size may be demonstrable roentgenographically. There should also be a satisfactory response to exercise, and the child must show an ability to sustain growth and development before the disease is considered to be inactive.

**Laboratory appraisal.** At present there is no specific laboratory test for rheumatic fever. However, two nonspecific tests, the erythrocyte sedimentation rate (ESR) and the C-reactive protein determination, are useful in patients with equivocal symptoms and in evaluating activity of the established disease.

**ERYTHROCYTE SEDIMENTATION RATE.** In patients with rheumatic polyarthrititis or carditis unaccompanied by congestive failure the ESR is almost always elevated. During congestive failure the ESR often becomes normal, but usually rises as soon as compensation returns. Since the ESR is normal in uncomplicated chorea, the finding of an elevated rate in a choreic patient often indicates cardiac involvement.

The erythrocyte sedimentation rate frequently remains elevated after the subsidence of all clinical symptoms, indicating that the rheumatic process is still active at a subclinical level. Patients should be kept in bed until the ESR becomes normal or at least shows a tendency to decrease.

In children with vague complaints of joint pains, frequent epistaxes, pallor, fatigue, bouts of abdominal pain, erythematous rashes or low grade fever, an elevated ESR suggests the possibility of rheumatic fever.

**C-REACTIVE PROTEIN.** The C-reactive protein is not normally present in blood and frequently appears in the serums of patients who are acutely ill with a variety of diseases, including rheumatic fever. As the patient improves, this protein disappears. In contrast to the ESR, which depends upon a number of factors (fibrinogen, globulin and number of red blood cells) and is affected by stimuli other than those of rheumatic activity, the C-reactive protein is a single substance detectable by a highly specific precipitin reaction. During congestive failure of active rheumatic carditis, the ESR is frequently normal, whereas the test for the C-reactive protein is usually positive.

*Leukocytosis* per se is a less reliable indication of a subclinical rheumatic infection than is the sedimentation rate. The rheumatic process should not, however, be considered quiescent when the white blood cell count is consistently above 10,000 per cubic millimeter, especially when there is a definite shift to the left of the polymorphonuclear cells. Persistence of anemia is also evidence that the infection is still active.

The *P-R interval*, which frequently becomes prolonged during the course of an acute

attack, usually returns to its previous length as the patient improves. In some patients, however, it becomes fixed and remains permanently prolonged, probably as the result of scarring of the conduction system. A prolonged P-R interval, therefore, does not always indicate rheumatic activity.

**Prognosis.** Though some children who have no preceding history of rheumatic disease are found to have rheumatic carditis, in most instances serious cardiac damage is the result of repeated severe rheumatic attacks. The prognosis for children who contract rheumatic fever before they are six years of age is usually graver than for those who have their first attack at a later age. This difference is related principally to the frequency with which carditis is the principal or sole manifestation in the initial attack in the younger age group and the frequency with which there is residual cardiac damage. Young children are also more susceptible to streptococcal upper respiratory tract infections and are thus more apt to have recurrences unless adequate prophylaxis is maintained.

The outlook for children in whom the rheumatic manifestations are mild with little or no evidence of cardiac involvement is good, whereas the prognosis of patients with persistent cardiac enlargement indicative of a chronic infection of the myocardium is poor. Children usually die as a result of further rheumatic infection rather than as a result of mechanical failure, and at autopsy fresh as well as old lesions are found. Even with fairly marked valvular deformities the heart is able to function more or less adequately, provided the cardiac muscle is in good condition.

There are no permanent changes in the joints after rheumatic polyarthrititis or in the central nervous system after chorea.

**Prevention.** It is now generally accepted that the initial and recurrent attacks of rheumatic fever can be prevented by the control of streptococcal upper respiratory tract infections.

**Initial attacks.** It is estimated that 1 to 3 per cent of untreated cases of pharyngitis due to group A streptococci are followed by rheumatic fever. The incidence of rheumatic sequels can be greatly reduced by treatment which eliminates streptococci from the upper respiratory tract. Penicillin is the drug of choice, and therapeutic levels must be maintained for ten to fourteen days. One intramuscular injection of 600,000 units of pro-

caine penicillin G combined with 600,000 units of benzathine penicillin G will give adequate levels for fourteen days. Oral administration of penicillin has the disadvantage that patients tend to discontinue the medication as soon as they feel well and hence do not receive treatment for an adequate length of time. Broad-spectrum antibiotics should be used only in patients known to be hypersensitive to penicillin and must also be continued for at least ten days.

Every patient with scarlet fever should be treated as outlined above. In the absence of a scarlatinal rash the clinical diagnosis of streptococcal pharyngitis is often difficult. The following signs and symptoms are sufficient to warrant treatment: fever of  $101^{\circ}$  to  $104^{\circ}$  F., pain on swallowing, an inflamed throat often with exudate, tender swollen cervical nodes, and leukocytosis of more than 12,000 per cubic millimeter.

**Recurrent rheumatic fever.** In known rheumatic subjects the incidence of recurrent rheumatic fever may be as high as 50 per cent after streptococcal pharyngitis. With each recurrence the danger of permanent cardiac damage increases. Since the symptoms of the streptococcal infection may be so mild as to escape attention, rheumatic subjects should receive continuous prophylactic therapy. At present three methods are available: (1) intramuscular injection of 1,200,000 units of benzathine penicillin once a month; (2) oral administration of penicillin, 200,000 units twice a day, preferably thirty minutes before breakfast and supper; (3) sulfadiazine, 0.5 gm. for children weighing less than 60 pounds, and 1.0 gm. for those weighing more than 60 pounds, once daily. The method selected depends on the patient and his family. Oral medication often fails because the patient forgets to take the medicine regularly. Hypersensitivity reactions to penicillin in children are uncommon, but may occur. Sulfadiazine occasionally causes toxic reactions during the first two months of administration which necessitate discontinuance of the drug. Urticaria and abdominal pain accompanied by fever may occur during the second to third week. Agranulocytosis sometimes develops, usually during the third to the eighth week, and therefore leukocyte counts should be obtained once a week during this period. If no untoward reactions occur during the first two months, sulfadiazine is well tolerated and has the advantage that a single daily dose taken at any time provides adequate levels.

**Prophylaxis against bacterial endocarditis.** Transient bacteremia, most commonly due to alpha streptococci (*Streptococcus viridans*), occurs frequently after dental extractions or tonsillectomy. These organisms may lodge on valves damaged by rheumatic fever. Routine prophylactic measures are not adequate protection. Rheumatic children should receive 200,000 units of oral penicillin four times a day for a total of five days; two days before, on the day of and two days after operation. In addition to the oral medication, on the day of the operative procedure 600,000 units of aqueous and 600,000 of procaine penicillin should be given intramuscularly approximately one hour before operation.

**Treatment.** No specific therapy which will terminate the activity of the rheumatic process is available. In any given case, irrespective of whether the clinical manifestations are mild or severe, it is impossible to predict how long rheumatic activity will persist or how much permanent cardiac disease may develop. Suppressive therapy is all that is available until the attack has run its course. Penicillin is of no value in alleviating the manifestations of rheumatic fever; however, since rheumatic activity may be prolonged by the presence of group A streptococci, it is advisable to give all patients with acute rheumatic fever or chorea an intensive course of penicillin for two weeks to eliminate these organisms from the body. The prophylactic regimen should then be instituted.

The response of rheumatic polyarthritis to salicylates is dramatic. The fever decreases, and the pain and swelling of the joints often subside within twenty-four to forty-eight hours. The erythrocyte sedimentation rate usually decreases, and the C-reactive protein disappears. The effect on the arthritic manifestations is so rapid and striking that salicylates are often given as a therapeutic test to differentiate other arthritides from those of rheumatic origin.

The effect of salicylates on carditis, on the other hand, is equivocal. Although they tend to improve the general condition and the temperature is reduced, the pulse rate usually remains elevated, the size of the heart does not decrease, and signs of congestive failure, when present, persist. Pericarditis, like polyarthritis, is an exudative reaction and often appears to respond to salicylate therapy. The duration of pericarditis is extremely variable, however, and symptoms often subside without treatment.

A standard dosage schedule for salicylate therapy has not been established. Intravenous administration has no advantages over the oral route. Either acetylsalicylic acid (aspirin) or sodium salicylate may be used, though most children prefer aspirin. A dose of 120 mg. (2 grains) per kilogram of body weight per day in four to six divided doses for the first forty-eight hours is commonly used. If the symptoms are alleviated, the dose may be reduced by one third, then by one half if improvement continues, and finally gradually discontinued. The duration of the attack cannot be predicted. The C-reactive protein should be negative and the erythrocyte sedimentation rate should have been decreasing for at least three weeks before therapy is discontinued. If a "rebound" of clinical symptoms occurs, therapy should be reinstituted. If the rebound is limited to laboratory observations, the deviations usually disappear without further treatment.

*Toxic reactions* characterized by tinnitus, nausea, vomiting and headache are frequent with large doses of salicylates, which may also cause hyperpnea by stimulation of the respiratory center. Salicylates also interfere with prothrombin synthesis, so that purpuric manifestations, ecchymoses and even hemorrhage may occur.

Children tend to tolerate salicylates better than do adults, but the tolerance of different children varies greatly. The simultaneous administration of sodium bicarbonate decreases the absorption of salicylates, thus decreasing the serum level, and has the same effect as lowering the dose.

Aminopyrine or phenylbutazone (Butazolidin) may be used in patients who cannot tolerate salicylate. Aminopyrine has a tendency to cause agranulocytosis; therefore weekly leukocyte counts should be obtained. Phenylbutazone is chemically closely related to aminopyrine, but is supposed to have a less deleterious effect on leukocyte formation.

*Corticosteroid therapy.* Similar results are obtained with ACTH, cortisone and prednisone. Since ACTH must be given parenterally, it is rarely used. Prednisone has less tendency to cause sodium retention than cortisone and is preferable.

The effect of corticoid therapy on clinical symptoms in acute rheumatic arthritis is similar to that with salicylates. The abnormal laboratory findings tend to disappear somewhat more quickly, however.

In acute rheumatic carditis the immediate effect is often striking. Fever, "toxicity" and

anorexia appear to be controlled more quickly than with salicylates. In many instances congestive failure disappears, provided the intake of salt is limited. Since the prognosis for patients with carditis severe enough to cause decompensation is almost always poor, the presence of this complication is a definite indication for corticoid therapy. Tachycardia usually persists even though the temperature becomes normal, the quality of the heart sounds improves, and a gallop rhythm, if present, disappears. In the absence of pericardial effusion the heart size usually does not decrease rapidly, and organic murmurs tend to persist.

When rheumatic activity cannot be controlled with salicylates, a good response is often obtained with a corticoid. Relapses or rebounds are frequently observed following premature withdrawal of hormone therapy, suggesting that, as with salicylates, these agents suppress but do not terminate the rheumatic process. However, the fact that congestive failure is often controlled by them suggests that the inflammatory reaction in the myocardium may be rapidly decreased. In contrast to the effect of corticoid therapy in acute rheumatic carditis, the response of patients with long-standing chronic myocarditis has been disappointing.

Corticosteroid dosage\* depends on the

\* Provided treatment is begun within two to three weeks of the onset, the following regimen may be used for the average patient with rheumatic carditis. To minimize rebound phenomena after termination of hormone therapy, some physicians prescribe aspirin during the period of gradual decrease of the dose of the corticosteroid. After cessation of therapy the child should be observed for three to four weeks for rebound phenomena.

1st week: prednisone, 60 mg./24 hours

2nd week: prednisone, 50 mg./24 hours

3rd week: prednisone, 40 mg./24 hours, and aspirin, 100 mg./kg./24 hours

4th week: prednisone, 30 mg./24 hours, and aspirin, 100 mg./kg./24 hours

5th week: prednisone, 20 mg./24 hours, and aspirin, 100 mg./kg./24 hours

6th week: prednisone, 10 mg./24 hours, and aspirin, 100 mg./kg./24 hours

7th week: omit prednisone; aspirin, 100 mg./kg./24 hours

8th and 9th weeks: aspirin, 70 mg./kg./24 hours

10th week: aspirin, 30 mg./kg./24 hours

Dosage schedules vary in different clinics. One plan provides about 2 mg. per kilogram per day of prednisone for the initial dose; another, 40 mg. a day for children under five years of age and 60 mg. for those over five years. In some clinics the termination of the tapering-off period varies from the eighth to the twelfth week.

severity of the symptoms, irrespective of age or weight. With adequate dosage of cortisone or prednisone for a few days, one may expect disappearance of fever and the C-reactive protein reaction and a decrease in the sedimentation rate.

Since steroid therapy masks symptoms of all kinds, children receiving such medication must be watched closely for serious complications and intercurrent infections. A careful history of the patient and the family in regard to tuberculosis, diabetes, hypertension, psychosis and ulcers helps to keep the physician alert for untoward effects. If the patient has a positive tuberculin reaction, isoniazid should be given. Steroid therapy should be postponed or discontinued in patients who have been exposed to or have such viral diseases as chickenpox, measles or poliomyelitis. Several deaths due to chickenpox have been reported in children receiving steroid therapy. The patient's blood pressure should be taken daily and the steroid discontinued if the diastolic pressure rises to 100 mm. or above. Frequent urinary examinations for glycosuria should be obtained. Intercurrent bacterial infections such as furuncles or pneumonia often occur. It is advisable to secure a roentgenogram of the chest at frequent intervals to rule out the latter possibility. These patients remain afebrile in spite of severe infections. The leukocyte count is usually elevated during steroid therapy and therefore in itself does not indicate an inflammatory process. Even with prednisone it has been found advisable to restrict the salt intake moderately and to add 1 to 2 gm. of potassium chloride to the diet daily.

Cushing's syndrome (moon face, acne, hirsutism, increased pigmentation, striae and abnormal fat distribution, including fat deposited in the liver) is a usual side effect which subsides when therapy is discontinued.

**Treatment of chorea.** At present there is no really effective treatment for chorea. Corticosteroids have not proved of definite value. Ketogenic diets have been tried, but no adequate data of a beneficial effect are available. Patients with chorea should be kept in bed in a room by themselves and should be cared for by sympathetic attendants. Both physical and mental rest are necessary. Padded sideboards for the bed are required for the most severe cases to avoid injuries. When choreiform movements are intense, the child should be fed by an attendant; adequate dietary intake should always be maintained. Various methods of treating chorea

have been tried, but since it is a self-limited disease (four to ten weeks), drastic measures are usually not necessary. The movements can in most instances be controlled by sedatives such as phenobarbital, Dilantin or tranquilizers. Opiates should be avoided. The child's progress can be followed by noting the improvement in handwriting.

**General measures.** Morphine is the most effective drug in controlling precordial pain and should be used in severe cases. If the patient is restless and apprehensive, a sedative such as phenobarbital should be given.

As long as the rheumatic process is active there is the possibility of progressive cardiac damage. Bed rest, therefore, is essential and may be necessary for a long time. As the patient improves, the inflammatory reaction in the myocardium subsides, and the heart tends to decrease in size. By reducing the work of the heart as much as possible, healing is promoted with the formation of a minimum of scar tissue.

Rheumatic patients often feel well, and it is difficult to keep them in bed. It is important to explain to the child that his illness is temporary and that rest is essential for recovery. Elementary education and occupational therapy must be provided. Prolonged bed rest can often be given more satisfactorily in institutions for convalescent care (see p. 231) than at home. It is generally considered desirable to keep rheumatic patients in bed until all laboratory as well as clinical evidence of rheumatic activity has disappeared. However, the child's personality must be taken into consideration. Prolonged confinement in bed makes some children irritable, and they are more active in bed than they would be otherwise. In such instances it is often better to permit a limited amount of activity in spite of abnormal laboratory findings. The diet must be adequate in all respects; though maintenance of nutrition is often a problem, overnutrition is not infrequent, especially among girls during the convalescent phase.

# Diseases of Mesenchymal Tissues

## (SO-CALLED COLLAGEN DISEASES)

This section contains descriptions of several diseases, grouped together because of similarities in symptomatology and pathology. Although such grouping has a certain logic and many advantages, it may be misleading. The etiology and pathogenesis of these illnesses are unknown. What is today considered a single disease may in actuality represent a variety of distinct entities, which may subsequently be differentiated as more critical techniques are available.

The diseases described here are (1) rheumatoid arthritis, (2) the Schönlein-Henoch syndrome, (3) dermatomyositis, (4) systemic lupus erythematosus, (5) periarteritis nodosa, (6) scleroderma, (7) morphea.

Generally, certain other diseases—rheumatic fever, acute glomerulonephritis, the nephrotic syndrome and chronic nephritis—are also considered to belong within this group; they are discussed in other sections. The clinical manifestations of some of these diseases are summarized in Table 101. The similarities which have in part led to their being grouped together are apparent. Differences, however, also exist, and each disease has characteristic manifestations which are rarely found in other members of the group.

### RHEUMATOID ARTHRITIS

#### (STILL'S DISEASE)

Juvenile rheumatoid arthritis is a protean systemic disease with an extraordinarily broad spectrum of manifestations. Even the forms of joint involvement by which the disease is characterized vary widely.

**Etiology.** The etiology is unknown. The onset is not generally associated with a preceding infection, and attempts to isolate causative infectious agents from blood, joint fluid or other potentially infected areas have failed. On the basis of pathologic similarities to various experimental diseases in animals, the illness has been classified by some as a

hypersensitivity response and by others as a direct infection with as yet unknown infectious agents, such as pleuropneumonia-like organisms, L-forms or protoplasts. A variety of factors influence the expression of the disease: (1) *Heredity*—There is a relatively high familial incidence of rheumatic diseases. (2) *Environment*—The incidence is presumably higher in temperate climates and in the spring months. (3) *Constitution*—The disease is more frequent in females under the age of six years. (4) *Psyche*—Psychologic stresses appear to be linked to the onset and to exacerbations. Thus it appears that the disease may be the response to an unrecognized exogenous stimulus (or stimuli), made manifest by the interaction of a variety of secondary factors.

**Epidemiology.** The incidence is not known, but the disease is not rare. Some estimates indicate that about an equal number of new cases of juvenile rheumatoid arthritis, juvenile diabetes and the nephrotic syndrome occur each year. The disease occurs almost twice as often in females as in males, even in the preschool age groups. The age at onset is rarely under one year; the median is about five years, and the mode, two to three years.

**Pathology.** The earliest noted pathologic change in the joints is periarticular swelling with edema; there is little synovial reaction or increase in the amount of joint fluid. Thereafter proliferation of the synovium and joint capsule occurs, and projections of thickened synovial membrane form villi which protrude into the joint cavity. At this stage there is an increase in joint fluid. Microscopically, there is edema, vascularization of the connective tissue and infiltration with lymphocytes. Later, as the synovial reaction spreads to the joint space, the articular cartilage undergoes change with ulceration and sometimes actual destruction. Change in the weight-bearing articular surface occurs late

in the disease. The synovial tissue may then entirely fill the joint space, leading to fibrous ankylosis. Bony invasion and fusion may then occur.

**Clinical Manifestations.** The onset may be sudden and fulminating with the classic pattern of spiking fever, adenopathy, splenomegaly, anemia and arthralgia, or the systemic manifestations may precede the arthralgia by a considerable time. In other instances the onset may be insidious, with

almost imperceptible development of joint stiffness, swelling, pain and eventual limitation of motion which may at times be localized for months or years to a single joint. The degree of systemic involvement, of which Still's triad (splenomegaly, lymphadenopathy and arthralgia) and less often hepatomegaly are a part, is usually greater, the younger the patient, occurring in 10 to 20 per cent of cases; 30 to 50 per cent of affected children have involvement of only one

FIG. 292. Characteristic posture of a child with rheumatoid arthritis, showing the anxious appearance and guarding of joints.

joint for a time, usually of the knee or ankle, but eventually almost all manifest polyarthritis.

Particularly in young children, pain and stiffness of the joints may be manifest initially without observable changes. Acutely ill children sit in bed with a characteristic posture (Fig. 292), appearing anxious and worried. They guard their joints against movement and desire to be left alone. The early changes in the joints are periarticular swelling and synovial thickening. Spindling or fusiform changes of the fingers as a result of this swelling (Fig. 293) are observed in over half of the children, even in infants with pudgy hands. There is limitation of motion, usually owing to pain; the joints may be warm, but not tender, and redness is not marked. Roentgenographically, the joint space may be widened, suggesting an increase in fluid; however, aspiration at this time is usually unsuccessful. Later the accumulation of fluid may increase. Destruction of the joints may follow with resultant deformity and sometimes with bony ankylosis. In some instances repeated episodes of severe arthritis occur without destruction, and sometimes without residual limitation of motion of the joints. Generally the symptoms of arthritis first become obvious in the joints of the lower

extremities. By the time, however, the child is usually brought to the physician, joint involvement of the upper extremities, characteristically symmetric in distribution and including the small joints, is present. Apparently any joint may be involved. Changes occur frequently in the spine, particularly obvious in the cervical vertebrae and in the temporomandibular joints, which may lead to micrognathia. Involvement of the sternoclavicular joints and costochondral junctions may mimic pleurisy; that of the chondral articulations of the larynx may result in hoarseness. During the acute phases of the disease major joint changes are obvious, but during quiescent phases involvement may be noted only by stiffness or limitation of motion. Morning stiffness or "gelling" is as frequent in children as in adults. Limitation of motion may lead to flexion contractures which more frequently cause residual deformity than does destruction of articular tissues.

Fever is the most striking systemic manifestation. In the acute phase the temperature may show wide diurnal fluctuations ( $99^{\circ}$  to  $107^{\circ}$  F.) or remain continuously elevated for prolonged periods. Sudden drops to subnormal levels may be precipitated by overvigorous antipyretic therapy, producing a shocklike state. In some instances there is only a low grade fever. Children, especially the younger ones, often have a characteristic evanescent rash (Fig. 294), usually at the height of the fever, consisting of small, dis-

FIG. 293. The spindling or fusiform swelling of the fingers in rheumatoid arthritis.

FIG. 294. The skin rash of rheumatoid arthritis.

crete, salmon-pink macules with pale centers. They may coalesce and become blotchy. The rash is found mainly on the trunk, is labile and can be increased by trauma or heat.

There are a variety of other systemic manifestations. Carditis is not infrequent, being reported in 10 per cent or more of cases; the lesions include pericarditis, frank myocarditis with electrocardiographic changes, consisting in P-R and Q-T prolongation and distortion of S-T segments, and cardiac enlargement with failure. Although murmurs are heard frequently during acute episodes, they are probably functional or hemic in origin; valvular deformities are conspicuously absent. The sudden appearance of anemia in addition to carditis is particularly serious. The cause of the anemia is unknown; there are aspects of increased blood destruction and of decreased regeneration. Such manifestations of polyserositis as pleuritis, hepatitis and abdominal pain suggestive of peritoneal involvement have been described. On rare occasions there are scattered pulmonary lesions which persist for a long time. Ocular changes, including iridocyclitis, may lead to blindness.

Tendons and muscles are involved by the disease process, atrophy usually becoming manifest late in the disease. Pigment changes of the skin, including vitiligo, occur over the involved joints. Superficial capillaries and venules become prominent. There may be changes suggesting vasomotor instability, and the skin appears pale and waxy. The hands and feet are likely to be cold; though at other

times the palms and soles appear red and moist ("liver palms"). Subcutaneous nodules may appear especially along the ulna and spine and over the occiput. The terminal complication of amyloidosis is no longer common.

**Diagnosis.** There are few early diagnostic radiologic changes. Swelling can be seen, and, as fluid accumulates, the joint spaces may be widened. The articular surfaces show marginal irregularities, and the bones become rarified, with a ground-glass appearance. Finally, if fusion takes place, the joint space becomes narrow and obliterated. Osseous maturation is advanced in the involved joints, which may lead to premature epiphyseal closure with resultant shortening and deformity.

There are no specific laboratory data. During the active phase the sedimentation rate is elevated, and acute phase reactants such as C-reactive protein appear in the serum. Anemia is frequently present, and the white blood cell count is usually elevated, although on occasion there is leukopenia. Febrile albuminuria is common. Serologic tests are not of much assistance. The antistreptolysin-O titer is seldom elevated; L.E. tests are negative; in adults serum factors which agglutinate sensitized sheep red cells, and gamma globulin-coated latex or bentonite particles have been described, but they are rarely found in children. Other evidences of protein reactions to stress are manifest by increases in serum globulins with reversal of the A/G ratio, by positive flocculation tests and by elevation of the serum complement.

In its florid and typical form this disease presents little difficulty in diagnosis. Early in the disease, when there are arthritis, fever and carditis, differentiation from rheumatic fever may be difficult. Evidence of a preceding streptococcal infection, either by history or by laboratory tests, may aid in differentiation. Often, however, the diagnosis depends upon the course of the disease.

Other causes of arthritis must be excluded. Among these are leukemia, pyogenic and tuberculous arthritis, rat-bite fever, and other collagen diseases, especially systemic lupus erythematosus. Arthritis indistinguishable from the usual rheumatoid disease is seen in patients with ulcerative colitis, regional enteritis, Whipple's disease, psoriasis and congenital agammaglobulinemia. Villous synovitis and allergic intermittent arthritis are probably related syndromes.

**Course and Prognosis.** The course is char-

acterized by recurrent exacerbations and remissions; generally each exacerbation is slightly less severe than the preceding one. The systemic manifestations of the disease become less marked, and the arthritic changes predominate. Gradually the disease appears to burn itself out over a period of two to ten years, becoming quiescent usually before puberty. Exacerbations in adult life have been reported.

During the acute phase cardiac failure and "toxicity" may threaten life. Once these hazards are passed, the immediate prognosis for life is good. The eventual prognosis will depend upon the residual deformity. Intercurrent infections, which were a major cause of death, can be controlled by the appropriate use of antibiotics. In rare instances the illness progresses uncontrollably to severe crippling or death many years after the onset. With adequate care more than three fourths of the children surviving the acute phase should be able to lead functionally adequate lives; over half of them will have complete functional recovery.

**Treatment.** Management of these children and their families constitutes one of the most severe tests of a physician's ability to treat the "whole child." The unpredictable exacerbations of the disease are discouraging and make evaluation of therapy difficult. There is a natural tendency to "shop" for medical help and to try "fad" cures. The eventual failure of any therapy to produce dramatic results may lead the family to "give up," allowing unnecessary crippling deformity to occur.

Adequate care demands a carefully planned long-term program. The parents and the child should come to know what to expect of the disease. The physical and emotional development of the child should be consistently followed and interpreted to the family. Optimal therapy may require at times some or all of the following: an orthopedist, a physical therapist, an ophthalmologist, an orthodontist, a psychiatrist, an occupational therapist, and aid from the child's school teacher. Their recommendations, however, should be channeled and coordinated through one person, the child's physician. This "team" approach is costly, and financial aid may be needed. The wide range of facilities required is usually found only in hospitals or group practice. However, these children need the individualized treatment, reassurance and restrained optimism which are best provided by the family physician. The schism represented by these requirements presents one of the

problems of therapy of chronic disease and has no easy solution.

The aims of therapy are to maintain motion in affected joints, to prevent deformity and to ensure as far as possible the normal growth and development of the child physically, mentally and emotionally. The first is best achieved by physiotherapy with active and passive exercises. Rest in bed does not seem to be beneficial except during acute febrile episodes, and may be harmful in predisposing to contractures. Weight bearing does not seem to increase the amount of joint damage. The activity of an ambulatory child often constitutes an adequate physiotherapy program. The child usually limits the activity of the most severely involved joints because of pain, while continuing to use, and so exercise, the rest of the body. In addition to this general activity, the patient and parents should be taught exercises designed to increase or maintain the range of motion in the most severely affected joints and to increase muscular strength.

No specific therapy is known. Although corticosteroids initially suppress symptoms to a remarkable degree, they do not induce a permanent remission. On discontinuance of therapy symptoms recur, often more severely than before. The therapeutic dose usually suppresses growth, and with prolonged therapy there is often a need to increase the dose; some patients become so addicted to therapy with corticosteroids that they cannot be weaned. Thus therapy with corticosteroids is indicated only when the disease is so severe that it threatens life, or when a short course of therapy might achieve an otherwise unobtainable goal, such as increased motion of joints to attain ambulation. Expected therapeutic gains should always be weighed carefully against the disadvantages.

Usually the initial dose required is about 4 to 5 mg. per kilogram per day (100 mg. per square meter) for cortisone and 1 mg. per kilogram per day (25 mg. per square meter) for prednisone. As soon as it is apparent that the corticosteroids are suppressing symptoms the dose should be gradually decreased until a minimum suppressive dose is reached. When the desired result is achieved, steroid therapy should be discontinued. On withdrawal, even if gradual, there is almost always a rebound of symptoms, which can sometimes be controlled by salicylates. Rebounds may, however, simply have to be weathered out. Occasionally the rebound is so severe that therapy with corticosteroids must be reinstituted. Under

such circumstances steroids may be required for years.

Salicylates are the most satisfactory suppressive medication; in doses adequate to maintain blood levels of 25 mg. per 100 ml. they will reduce fever and alleviate pain and stiffness. From the long-term point of view they are as effective as the corticosteroids and have fewer and less severe side effects. To maintain adequate blood levels initially, about 100 mg. per kilogram of aspirin divided into four or six doses are needed daily. There is considerable individual variation, however, in the levels obtained and in the therapeutic or toxic response. If blood levels are checked and the patient's reactions, particularly for toxicity, are observed, the medication can be given for years. Side effects other than toxicity from excessive levels are rare. An enteric-coated medication can be used for the night dose to ensure an adequate blood level for the following morning.

Other therapeutic agents which have been used include gold, phenylbutazone, chloroquine and nitrogen mustards. None at present offers sufficient advantages to warrant the dangers of their toxicity, except as it is used in a carefully controlled clinical study.

The comfort achieved by adequate salicylate medication usually allows full participation in a program of physiotherapy. With encouragement from parent and physician most children can lead active lives, attend school, and compete with their peers in most activities except those of strenuous and competitive sports. The use of hot morning baths often tends to reduce the stiffness from night "gelling" and helps to get the child ready for school. The parents become a pivotal point for therapy, and they often develop individualistic methods to help their child in everyday tasks. In accepting responsibility they adjust to the situation more adequately. Only rarely do parents become overwhelmed, but even in such instances patient reassurance will usually enable them to utilize their own potentialities.

### ANAPHYLACTOID PURPURA

(SCHÖNLEIN-HENOCH SYNDROME, ANAPHYLACTOID OR ALLERGIC NON-THROMBOPENIC PURPURA)

The term "Schönlein-Henoch syndrome" includes Schönlein's purpura (purpura with arthralgia), Henoch's purpura (purpura with visceral manifestations) and anaphylactoid or allergic nonthrombocytopenic purpura. The

word "syndrome" is preferred because the illness is a polymorphic systemic disease. The skin lesion, which is not always purpuric, is the most obvious but probably the least important sign; the visceral lesions are less easily recognized, but far more serious.

The primary manifestations are due to angitis. There are no changes in the clotting mechanism or in the blood or blood-forming organs which might lead to spontaneous bleeding.

**Etiology.** The etiology is unknown. In rare instances the onset or exacerbations of the disease may be linked to contact with some specific substance, in which case allergy seems to play a distinct role. Family history of allergy in these patients is not significantly increased. About one third of the cases follow closely an upper respiratory tract infection. *Beta hemolytic streptococci* can be cultured from the throats of about half of these, but a remarkable rise in antistreptolysin-O titer is unusual. Attempts to identify causative agents have otherwise been unsuccessful. Pleuropneumonia-like organisms have been found in blood cultures, but their presence is difficult to interpret.

Osler called attention to the similarity between this syndrome and serum sickness. Lesions resembling those of this disease have been produced in animals by injection of antibodies to the endothelial lining of their arteries. Although pathologic similarity cannot be equated with identity, it seems possible that this disease, like systemic lupus erythematosus, represents one type of hypersensitivity response (perhaps auto-immune) to a variety of antigenic stimuli.

**Epidemiology.** The incidence is not known, but this disease is not rare. There has been an apparent increase in recent years. Males are attacked twice as often as females. It affects all races; the recorded incidence may be lower in Negroes, owing to the difficulty in recognizing the rash. The age of onset is rarely less than one year; it is most common between three and seven years. The median and mean age of onset is five years.

**Pathology.** There is a paucity of pathologic data relating to this disease. Skin biopsies show the primary reaction to be an acute inflammatory exudate containing polymorphonuclear and round cells around the small vessels of the corium; eosinophils may be present, and the number of erythrocytes varies with the degree of purpura. Capillaries are generally involved, although changes in precapillary arterioles and necro-

tizing arteriolitis have been described. The pathologic difference between this disease and periarteritis nodosa is only one of degree. In the latter, medium-sized arteries are affected. Adjacent to the vascular changes, there is edema and swelling of the collagen fibrils. The early changes in the kidney as revealed by renal biopsy are characterized by endothelial proliferation and focal fibrinoid occlusion of the glomerular capillaries, resembling those of early systemic lupus erythematosus. Later the lesions are said to resemble those of subacute nephritis.

**Clinical Manifestations.** There is usually a progression of symptoms similar to the sequence in serum sickness. In some instances about a week or two following an infection, in others without a preceding infection, arthralgia and/or abdominal pain appear. This is followed within hours to a day or two by a skin rash. Sometimes all occur simultaneously; less frequently the rash precedes the visceral manifestations. There is generally some malaise and, in about half of the cases, a low grade fever. Rarely the onset is fulminating.

The skin changes are variable; classically, the lesion begins as an urticarial wheal. With varying rapidity a small pink or red punctum appears within the center of the wheal. Initially it blanches on pressure, but as it spreads and a variety of other maculopapular erythematous lesions appear, the ability to blanch is lost. Thereafter the lesions may become petechial or purpuric. The purpuric areas progress in the usual manner of ecchymoses, changing from red to purple, becoming rusty and eventually fading (Fig. 295).

The skin lesions appear in crops, but at any one time there may be a variety of different lesions. In some patients the lesions will be only petechial, and in others they never become hemorrhagic. All the various skin changes of erythema multiforme have been described, and angioneurotic edema involving the eyelids, lips, joint areas and the backs of the hands and feet is often an associated finding. The urticarial lesions are not usually pruritic.

In more than three quarters of instances there are symptoms referable to the gastrointestinal tract. The most common complaint is colicky abdominal pain, often associated with vomiting. Blood, either chemically or grossly demonstrable, is found in the stool of about half the cases. The sudden onset of acute abdominal pain and vomiting, with or

without melena, occasionally leads to laparotomy. It is unusual to find anything more than edema, peritoneal exudate, enlarged mesenteric nodes, and petechiae; infrequently there is intussusception with gangrene of the intestine.

Involvement of the joints, usually of the knees or ankles, is the predominant complaint in about two thirds of cases. There may be mild pain or swelling, or both. Motion may be limited, but rarely to the extent that it may be in rheumatic fever. When swelling is present, it usually consists of periarticular edema; synovial thickening is uncommon. The swollen joints may be warm, but they are not red or tender. The fluid within involved joints is serous and not bloody. The joint changes are evanescent and do not leave residual deformity.

Renal involvement is the most serious manifestation and occurs in about half of the cases at some time during the course of the disease. On occasion there is only albuminuria, but most often there is also gross or microscopic hematuria, with casts and other cellular elements. Generally these changes become apparent within the first two weeks of the disease, but they have been first noted after the skin and joint manifestations had become quiescent. About half of the children with renal involvement also have azotemia or hypertension, or both. The hypertension can be severe enough to cause encephalopathy and convulsions, as may be intracerebral angiitis, which also occurs; it may be impossible to differentiate the two conditions clinically. Chronic nephritis may be a residual (see Prognosis).

**Diagnosis.** *Laboratory examinations* are not diagnostic, but may aid in management. Unless blood loss has been great, there is no anemia. The sedimentation rate is elevated, and acute phase reactants (C-reactive protein) are present in the serum. The white blood cell count is increased in over half of the cases, and eosinophilia occurs occasionally. Platelet counts, bleeding time, clotting time and clot retraction are within normal limits. The tourniquet test is usually negative, although the trauma of the tourniquet may induce the local appearance of purpuric skin lesions several hours later. With renal manifestations of the disease, albuminuria or hematuria, or both, may occur. In children with gastrointestinal bleeding the stools may be bloody or found to contain blood chemically. Serologic tests do not assist in diagnosis; the antistreptolysin-O titer is rarely

elevated, and the L.E. and rheumatoid serum factors are not found. The serum complement titer may be elevated, distinguishing this disease from acute glomerulonephritis, in which the complement titer is low.

The urticarial lesions of this disease and the characteristic polymorphic nature of the erythematous eruptions when they appear usually allow easy differentiation from the hemorrhagic diatheses and from septicemia. In addition, the patient with septicemia usually appears more acutely ill. Differentiation from some of the other collagen diseases is more difficult. The clinical manifestations of periarteritis nodosa are related to the involvement of larger arteries; peripheral neurologic changes often occur, and cardiac manifestations are more common. However, the distinctions are simply a matter of degree, and at times no distinction can be made. It is also probable that the erythema multiforme group of diseases represents a variant of the same process. It has been suggested that the Schönlein-Henoch syndrome may occur without skin lesions, when the diagnosis must be based on the visceral and/or joint changes.

**Course and Prognosis.** The course is extremely variable. The average duration of symptoms is about six weeks; the illness has been known to smoulder for as long as one to two years, however. In rare instances there may be apparent exacerbations and remissions. More often the disease is mild, lasting only a few days and being manifest merely by transient joint changes and a few purpuric spots.

During the acute phase of the disease death may occur from gastrointestinal involvement, renal changes, hypertension or intracranial bleeding. The mortality rate in the acute phase is not known; it is probably less than 2 per cent. If death occurs later, it is usually from renal complications. The approximate incidence of such deaths is unknown. Renal insufficiency may not become manifest for several years after subsidence of the initial phase of the illness. It is variously estimated that 5 to 25 per cent of children with renal involvement have persistence of abnormal urinary findings for years and that some of them have loss of renal function as measured by the glomerular filtration rate. The majority have no residuals.

**Treatment.** There is no specific therapy. In the rare instances in which a specific allergen can be proved the patient should be kept from contact with it. When the disease seems to follow closely a bacterial infection,

as, for example, a streptococcal one, the infection should be treated vigorously to eliminate the organism. Eradication of foci of infection such as carious teeth or sinusitis does not seem to affect the course of the disease. The influence of bed rest or limitation of activity on the course and prognosis is not known, but during the acute phase, conservative management with limitation of activity is indicated.

In the acute phase the patient's life may be endangered by hemorrhage secondary to the vascular lesion. Intestinal obstruction may necessitate operation. The associated hypertension and hypertensive encephalopathy respond to hypotensive agents (see p. 1040). Close attention should be paid to the fluid requirements of patients with severe gastrointestinal and renal involvement.

Corticosteroids may give symptomatic relief and modify the hemorrhagic manifestations; they do not appear, however, to influence the course of the illness. With discontinuation of short-term steroid therapy symptoms again become apparent in almost all instances. The use of steroids does not appear to benefit the renal lesions, and there is experimental and clinical evidence to suggest that under some circumstances they may have an adverse effect. Thus the use of adrenal steroids still must be considered to be on an experimental basis; dosages are not established, but are probably similar to those recommended for rheumatoid arthritis.

Relapses are infrequent, but if one should occur, search for an offending allergen should be reinstituted. In children with residual renal damage the usual program for chronic renal disease should be followed.

## DERMATOMYOSITIS

Dermatomyositis involves many systems, but is characterized primarily by nonsuppurative inflammation of striated muscle, with which cutaneous lesions are usually associated. In the rare instances when only muscle is involved, the disease may be termed polymyositis. Pathologic changes are generally found in many organs. Owing to the characteristic perivascular lesions in involved areas, the disease is generally classified as one of the mesenchymal diseases.

**Etiology and Incidence.** The etiology is unknown; there is no convincing evidence that infection plays any role. In adults there is a frequent association with carcinoma; no such relationship is found in children. Mus-

culoskeletal changes produced experimentally by dietary deficiencies in animals have no counterpart in the manifestations of dermatomyositis in humans. Owing to the similarity of the tissue changes to other mesenchymal diseases, the illness is postulated to be a form of hypersensitivity reaction.

Dermatomyositis is not common. In children it occurs less frequently than rheumatoid arthritis, but more frequently than systemic lupus erythematosus. It is seen most often in the five- to twelve-year age group. Girls are affected more often than boys (3:2). It has occurred in twins. There is no racial predilection.

**Pathology.** Tissue obtained by biopsy is not necessarily diagnostic, but may provide supportive evidence. The pathologic lesions occur at the junction of skin and muscle and are irregularly distributed. In the muscle bundles there are vacuolization, centralization of nuclei, degeneration, infiltration between bundles, and perivascular changes. The vascular lesions usually involve small muscular arterioles. There is perivascular cuffing with round cells and medial proliferation. Granular deposits suggesting platelet thrombi sometimes occur.

**Clinical Manifestations.** The onset is insidious. The initial evidence is usually weakness or easy fatigability. This is generally apparent first in the legs, although involvement of the shoulder girdle may exist earlier. Weakness is frequently associated with stiffness of the muscles. The gait becomes awkward, and the muscles sore and painful. The degree of weakness may vary from slight to extreme. All the muscles of the body may be affected. Involvement of those of respiration and deglutition is of particular importance; when severe, this may lead to respiratory difficulty, aspiration, and death. Affected skeletal muscles feel inelastic, brawny or indurated. The skin, subcutaneous tissues and muscles are thickened and may be tender. Edema, which pits poorly, is sometimes present.

The characteristic skin lesion consists of a slight erythema, induration and occasionally scaling over the malar areas and the bridge of the nose in a butterfly distribution. It is rarely as severe as the similarly located rash of systemic lupus erythematosus. Perhaps of more diagnostic significance is a peculiar violaceous or faintly erythematous discoloration on the upper eyelids (Fig. 297), which is usually present in dermatomyositis and occurs rarely in other diseases. It may oc-

asionally be associated with periorbital edema. Other skin areas are also involved with a variety of lesions. The skin over involved extremities appears tight, glossy or scaly. In long-standing disease atrophy occurs, and the skin becomes tightly bound to underlying tissues. The fingers may become tapered. Over the extensor surfaces of the joints, particularly the knuckles, the skin becomes erythematous, atrophic and scaly (Fig. 299). Fine blood vessels become prominently visible (*poikiloderma vasculare atrophicans*), and these areas later have pigmentary changes. Late in the disease deposits of calcium may occur in the subcutaneous tissues, muscle and fascia (*calcinosis universalis*). These may be manifested by stony-hard plaques or small nodules, which sometimes break down and are extruded in semi-solid or solid form.

Low grade fever is most often present, and other evidences of systemic involvement, such as mucous membrane lesions, lymphadenopathy, hepatosplenomegaly, renal, gastrointestinal and cardiac changes, have been reported, but are far less common.

The sedimentation rate may be elevated. The destruction of muscle is responsible for increased urinary excretion of creatine and for elevation of the serum transaminase level. Serologic studies have not shown L.E. cells or rheumatoid factors. The antistreptolysin-O titer is not elevated. The serum complement is sometimes higher than normal. On rare occasions the urine will contain albumin. With gastrointestinal involvement there may be gross or occult blood in the stool. Roentgenograms will reveal calcium deposits if *calcinosis* exists. Electromyograms demonstrate fibrillary changes.

**Diagnosis.** In its typical form dermatomyositis presents little diagnostic difficulty. In the differential diagnosis of this disease various neuromuscular disorders such as poliomyelitis, and illnesses having predominantly muscular lesions, such as trichinosis, should be considered. The skin lesion on the face may be mistaken for *systemic lupus erythematosus*, which can be established by demonstration of the L.E. cell phenomenon and by involvement of other organs, such as the kidneys. *Scleroderma* can be distinguished from dermatomyositis by its characteristic dermal pattern with "hide-binding." At times the onset of dermatomyositis is so insidious that a period of observation is needed before the diagnosis can be established.

**Course and Prognosis.** The case fatality rate is approximately 40 per cent. Death is

generally related in some manner to palato-respiratory involvement. Recovery is limited only by the residual deformity. The disease slowly becomes inactive, usually over a period of one to three years. Exacerbations are uncommon after such a period. Of those who survive, a few will have severe contractures with crippling deformities; more than half of them will have few residuals and will be able to lead an active, normal life.

**Treatment.** Functional recovery depends upon prevention of contractures and correction of deformities. There is no substitute for vigorous physiotherapy, carefully planned and supervised to make it acceptable to parents and patient. Such physiotherapy should be instituted in spite of active disease. Orthopedic assistance should be sought early. Absolute bed rest or immobilization in any form is contraindicated, since it predisposes to contractures. Early ambulation, aided by symptomatic therapy, is the optimal form of treatment.

Corticosteroids aid in such therapy by providing symptomatic relief. In some cases this is striking and allows earlier physiotherapy and ambulation than would otherwise be possible. Symptomatic relief may be accompanied by a return of muscle power. Initially the corticosteroids should be given in high doses (cortisone, 4 to 5 mg. per kilogram per day or 100 mg. per square meter per day; prednisone, 1 mg. per kilogram per day or 20 mg. per square meter per day in two or three divided doses). As soon as it is apparent that symptoms are being suppressed (usually seven to ten days) the dose should be gradually decreased over a period of weeks, watching carefully for rebound phenomena, until the minimum suppressive dose is reached. Usually this level (1 to 2 mg. per kilogram per day or less than 37 mg. per square meter per day of cortisone; 0.3 to 0.4 mg. per kilogram per day or 7.5 mg. per square meter per day of prednisone) allows prolonged therapy without the occurrence of serious cushingoid side effects or suppression of growth.

The administration of corticosteroids must be viewed with certain reservations. They do not seem to alter the mortality from this disease. Prior to their use death was usually from palatorespiratory involvement; now it is more often from gastrointestinal crisis and hemorrhage. It is suspected that administration of corticosteroids may accentuate some of the pathologic changes found naturally in this disease.

## SYSTEMIC LUPUS ERYTHEMATOSUS

(LUPUS ERYTHEMATOSUS DISSEMINATUS)

Systemic lupus erythematosus in children is a rare condition which, if untreated, seems to be almost uniformly progressive and fatal. In adults chronic and subacute variants of the disorder are seen; these are infrequent in children. The disease represents the prototype of mesenchymal diseases. In it the involvement of multiple systems is most readily apparent, and for this reason it is of considerable interest to the clinician, the pathologist and the immunologist. The affected person exhibits an extraordinary propensity to form abnormal antibodies, including ones against his own tissues. Auto-immune antibodies are responsible for the development of hemolytic anemia and for the formation of the L.E. cell phenomenon. They may also be involved in the formation of the hematoxylin body which is characteristic of this disease, and perhaps in all the many varied pathologic changes that occur. Such evidence has led to the postulate that this illness is an auto-immune hypersensitivity reaction; that these patients create antibodies against their own tissues and in so doing destroy themselves. Why an organism should fail to recognize its own tissue components as "self" and treat them as foreign substances, forming antibodies to them, is an immunologic paradox of considerable biologic interest.

The mechanism by which the presumed immunologic defect is precipitated is unknown. In a few instances exposure to known heterologous antigens seems to be linked to the onset of the disease. Children as young as two years have been affected, but the usual age at onset is beyond eight years. Girls are affected much more frequently than boys (9:1). The disease has been described in siblings, and there may be a familial predisposition. All races are attacked.

**Pathology.** Changes occur in all mesenchymal tissues. The proliferative and degenerative changes of collagen and the formation of fibrinoid are characteristic. Changes in small arteries and arterioles occur throughout the body. In the spleen these are associated with perivascular fibrosis and proliferation, which forms concentric rings. In the kidneys the basement membranes of the glomerular capillaries become thickened and deeply eosinophilic. Extreme changes of this kind appear like wire loops. Accumulations of

material containing desoxyribose nucleic acid (DNA) in so-called hematoxylin bodies are found.

**Clinical Manifestations.** The onset is usually difficult to determine. Premonitory symptoms, such as intermittent fever, vague arthralgia or episodes of thrombocytopenic purpura, are frequent. These may predate the florid appearance of the disease by many months. In a few patients the disease appears suddenly, systemic symptoms of fever, malaise and anorexia occurring simultaneously with the pathognomonic butterfly rash.

The butterfly rash (Fig. 298) is a striking finding. It appears in more than three fourths of affected children. Usually it is markedly erythematous, covering the malar areas and most often spreading over the bridge of the nose. The rash may be photosensitive. Although involvement of the lower eyelids is common, the upper lids are usually spared. Periorbital edema, in the absence of generalized edema, is uncommon. The rash may spread to involve the entire face, the scalp, neck, chest and upper arms in a patchy manner. The lesions may become bullous and secondarily infected.

Other skin rashes are also found. Minute erythematous puncta that appear on the palms, soles and finger tips are particularly distinctive (Fig. 300). Such spots are apparently secondary to vascular changes and may be petechial. Further infarction may lead to actual loss of tissue from the involved areas. Splinter hemorrhages and capillary tortuosity are seen in the nail beds. The punctate lesions on the mucous membranes of the mouth probably result from an identical pathologic process. Purpura, sometimes associated with thrombocytopenia, appears on dependent or traumatized areas.

Of the many evidences of systemic involvement, fever is the most common. Almost every patient is febrile at one time or another during the course of the disease. Generally there are irregular, moderate to high spikes of fever associated with malaise, anorexia and debility.

Arthralgia is another frequent finding. The affected joints may be red, warm and swollen. When such findings precede other symptoms, this illness may be confused with rheumatic fever or rheumatoid arthritis. Usually large joints are involved, but stiffness of the hands is seen. Polyserositis with pleurisy, pericarditis and peritoneal reactions are characteristic of the disease.

Hepatomegaly, splenomegaly and generalized lymphadenopathy are present in about half of affected children. About two thirds of them have some form of cardiac involvement, as evidenced by variable murmurs, friction rubs and electrocardiographic changes. Verrucous endocarditis (Libman-Sacks syndrome) is found frequently at postmortem examination.

More than three fourths of these patients have clinical evidence of renal involvement, generally manifest by hematuria, albuminuria and cylindruria. Hypertension and azotemia may be present. Once renal disease has become apparent, it characteristically progresses relentlessly, with progressive loss of renal function. Renal or cardiac involvement or intercurrent infection is usually the cause of death. In a few patients urinary abnormalities have disappeared, and renal function appears to have been unimpaired. Whether such remissions are permanent is at present unknown.

**Laboratory Data.** The demonstration of the L.E. cell phenomenon described by Hargraves is the most useful laboratory test. When the serum of the patient is mixed with white cells and a source of nucleic acid (e.g., white cell nuclei), the particles of nucleic acid are coated with gamma globulins from the serum and are phagocytized by the polymorphonucleocytes. The ingested particles form large cytoplasmic inclusion bodies, forcing the cell nucleus to the periphery (Fig. 296). Antibodies to other tissue components have been described, but this one is the most easily demonstrable. The serum factor responsible for the L.E. cell phenomenon can be found in almost all patients with the disease. It is probably relatively specific, being found rarely in any other illness.

Anemia, often partially hemolytic, occurs, as do thrombocytopenia and leukopenia. The sedimentation rate is usually elevated, and there are acute phase reactants in the serum. The proteins generally show a remarkable increase in gamma globulins. Flocculation tests are usually positive, and some of the patients have falsely positive serologic tests for syphilis. There may be difficulties in typing and cross matching blood, owing to the presence of antibodies to heterologous erythrocytes. Auto-agglutination of the patient's own red cells occurs. The serum complement titer is depressed. The urine contains erythrocytes, albumin and casts. Chemical evidence of renal insufficiency, such as elevation of the

blood urea nitrogen or abnormal concentrations of serum electrolytes, may appear terminally.

**Course and Prognosis.** Evaluation of the course and prognosis and of efficacy of therapy has been complicated by an increased frequency of recognition. In children the mortality, even with treatment, appears to be extremely high; more than half die within one to two years of diagnosis. Although permanent remissions must be uncommon, current experiences with steroid therapy suggest that they may occur.

**Treatment.** The symptoms can generally be suppressed by administration of cortisone or prednisone. Whether these hormones alter the prognosis or affect the basic processes responsible for the disease is unknown. The continuous suppression of symptoms by their use is the only available therapy, and the high mortality of untreated cases justifies their long-term use. Initial doses are similar to those used in rheumatoid arthritis (p. 919). The dose should then be adjusted to the least amount giving consistent suppression of symptoms; the dose may have to be altered as the severity of the disease changes. Administration should probably be continued for years. Severe clinical rebounds generally occur if the corticosteroid is withdrawn within a shorter time. On such a regimen the patient can often lead an active ambulatory life; however, as a rule the renal lesion tends to progress. The widespread angiitis may predispose to the untoward usual side effects of the corticosteroids, and salt retention, edema and hypertension must be carefully watched for. Recently it has appeared that some antimalarial compounds, such as chloroquine, may also suppress symptoms. These drugs can be given as adjuncts to steroid therapy.

## PERIARTERITIS NODOSA

### (POLYARTERITIS)

One of the common denominators of the mesenchymal diseases is angiitis. Involvement of *small vessels*, characteristic of the Schönlein-Henoch syndrome, is common also in systemic lupus erythematosus and dermatomyositis. When *great vessels*, such as the aorta, are affected, the resultant illness has been described as "pulseless disease" or Takayasu's syndrome. When *medium-sized* or *small arteries* throughout the body are involved, resulting in actual destruction, aneurysmal dilatation and proliferation of the

vessel wall, the disease is termed periarteritis nodosa. The diagnosis is based on pathologic changes, and the disease is defined in these terms.

The *etiology* of periarteritis nodosa, a rare disease in childhood, is unknown. Experimental studies suggest that the lesions are a form of hypersensitivity response; they have been described as a sequel to serum sickness and to sulfonamide reactions. The disease affects all races and all ages. It is more frequent beyond the age of six years, but has been described in infants. Adult males are affected four times as often as adult females. This sex differentiation is not apparent in childhood.

The *symptomatology* of the disease is explicable by the pathologic changes. Signs of systemic illness such as fever, anorexia, lethargy, weakness and weight loss are usually present. Vague fleeting pains in the extremities are common. Severe sudden pain may result from occlusion of mesenteric or coronary arteries. Skin eruptions of unusual form are seen; they are generally macular or urticarial, but may be hemorrhagic. Peripheral nerves adjacent to involved arteries are affected, giving rise to the usual findings of peripheral neuritis. In some patients the aneurysmal dilatations along peripheral vessel walls are palpable, simulating subcutaneous nodules. Infarction of large masses of tissue may occur; involvement of cerebral vessels may result in convulsions or coma, as may also hypertension, due to vascular changes per se, or secondary to renal involvement.

Albuminuria and, less often, hematuria occur. Anemia and leukocytosis, which may be marked, are common. In many instances there is also a striking eosinophilia. Terminally there are likely to be the findings of renal insufficiency. Electrocardiographic changes may indicate carditis.

Periarteritis nodosa is readily confused with many other mesenchymal diseases. The *diagnosis* is based primarily on the finding of histologic changes in involved tissues, which may not be specific, but the type of blood vessel involved and the tissue response do provide a basis for differentiation. Further, the uniformity of symptomatology in many patients with these pathologic changes suggests that a separate categorization is justified. The diagnosis can be made only through a high index of suspicion, which may be confirmed by biopsy.

The *prognosis* appears to be poor. The

diagnosis is made most frequently at autopsy, but some patients have survived. There is no specific therapy. The value of therapy with corticosteroids is in doubt.

## SCLERODERMA

### (HIDEBOUND DISEASE)

Scleroderma is a rare progressive, generalized, chronic inflammation, usually perivascular, of the skin and subcutaneous tissues and at times of the adjacent muscle; the viscera may also be involved. Little is known about its manifestations in children. The inflammatory changes lead eventually to fibrosis of the involved areas, and the skin becomes firmly adherent ("hidebound") to the underlying tissues. The affected areas feel cool, smooth, waxy or wooden; contractures develop and interfere with motion. Affection of the fingers and toes, known as *sclerodactylia*, results in Raynaud-like symptoms. Changes in the face give an immobile masklike appearance and may interfere with deglutition.

The etiology and pathogenesis are obscure. In addition to the involvement of the skin, there are visceral changes. Those in the esophagus lead to gastric reflux and aspiration pneumonitis. The latter, in conjunction with the primary pulmonary fibrosis, may seriously impair respiratory function. Cardiac involvement may result in progressive congestive failure, or renal dysfunction may be the terminal event.

The course and prognosis in children are poorly defined. Generally the disease is chronic rather than acute, and spontaneous remissions and relapses occur. In some instances there is apparently partial or complete recovery.

No specific therapy is known. Physiotherapy and orthopedic procedures should be used to prevent or correct contractures and deformity. The efficacy of therapy with corticosteroids is in doubt, but it probably should be given a trial early in the course of the disease.

## MORPHEA

### (LINEAR OR LOCALIZED SCLERODERMA)

Morphea is a benign, self-limited localized disease of the skin and subcutaneous tissues; in contrast to scleroderma it does not involve the viscera. In childhood, morphea, although rare, occurs more often than scleroderma.

The first signs are usually patchy lesions of the skin and subcutaneous tissues. These

often have a linear pattern similar to the dermal distribution of peripheral nerves. During the acute phase the involved areas are erythematous and edematous. As the disease progresses the inflammatory process subsides, usually becoming quiescent first at the center of the lesion. The skin lesions in this stage have a violaceous, sometimes elevated, border and a white or yellow waxy-appearing center. The lesions eventually coalesce with the disappearance of the dermatomal pattern, and an entire extremity or a large portion of the body may be involved. With subsidence of inflammation extensive scarring of the area occurs. The resultant fibrosis leads to deformation of the involved tissues; contractures are common and may be severe enough to limit the growth of an affected limb.

Information on the duration of the active phase is lacking. Generally the disease becomes quiescent over a period of months or years. Once it has become quiescent, reactivation is unusual. The prognosis for life is good, but that for deformity is poor. The course is varied and unpredictable, and data relating to the efficacy of the corticosteroids or other forms of therapy aimed at preventing progression of the inflammatory process are not available. When the disease has become quiescent, surgical procedures may be effective in improving function as well as for cosmetic repair.

# Diseases of the Blood

The formation of blood cells begins in the fetus about the fourth week of gestation in mesenchymal tissue, initially in the yolk sac, then successively in body mesenchyme, in liver, in spleen, thymus and lymphatic tissues and finally in the bone marrow. For the first six months of fetal life the liver is the most active site of hematopoiesis, but after the third month the marrow becomes increasingly active, and at term blood formation resides almost wholly in it, with only limited activity in lymphatic tissue and in the spleen and liver.

In the infant and young child nearly all the marrow is engaged in active hematopoiesis. After completion of growth, blood cell production in marrow is limited to the ends of the long bones, the vertebrae and certain flat bones, all of which contain red marrow. The other marrow is then largely yellow fatty

tissue, but it retains the ability to form new blood cells in times of exceptional need. When all the marrow is actively hematopoietic, as it normally is in children, additional demands for blood may be met by myeloid metaplasia in the reticuloendothelial tissues, especially in the liver, spleen and lymph nodes. This extramedullary hematopoiesis may result in enlargement of the involved organs.

In general, erythrocytes, granulocytes and platelets are formed in bone marrow, and the cells of the lymphocyte family, including the monocytes, are largely formed in lymphatic tissue, some of which is in marrow. It is only by studying directly or indirectly the states of the hematopoietic tissues as well as that of the spleen, as an organ of blood destruction, that it is possible to understand the meaning of what is observed in the peripheral blood.

## DISORDERS OF RED BLOOD CELLS

**Physiology.** The principal function of the red blood cell is to carry oxygen to tissues and carbon dioxide from them. Hemoglobin also contributes buffering action in defense of the pH of blood.

The largest part of the hemoglobin in the fetus (fetal hemoglobin) is biologically different from adult hemoglobin. It is more nearly saturated at low oxygen tensions than is adult hemoglobin. Transfer of oxygen from maternal blood is enhanced by this difference and by a distinctive property of maternal blood during pregnancy which facilitates release of oxygen at tensions suitable to fetal hemoglobin. An analogous relationship exists for dissociation of carbon dioxide and hemoglobin. The production of fetal hemoglobin falls to a low level within a few months, and hemoglobin of adult type is formed in increasing amounts. Under unusual circumstances, as in thalassemia and sickle cell disease, there is interference with production of normal adult hemoglobin, and the production of fetal hemoglobin may persist.

The formation of red blood cells requires the presence of healthy primordial elements in marrow. Vitamin B<sub>12</sub>, folic acid and vitamin C are closely related to the production of red blood cells. The first two are related to, if not jointly identical with, the maturation factor, which is essential to proper maturation of erythrocyte precursors. Vitamin C is thought to be necessary for the conversion of folic acid to its biologically active form, leucovorin (citrovorum factor, CF, folinic acid). These factors are closely related in body economy to the formation of nucleoproteins, particularly as they contribute to the formation of thymidine and thymine. Other vitamins, such as thiamine, riboflavin and pyridoxine, have a more general relation to blood formation as general growth factors.

Adequate stores of iron and protein are necessary for the synthesis of hemoglobin. The iron is derived from antenatal and postnatal dietary sources and from the destruction of hemoglobin in the body, the iron of

which is ordinarily reused. The principal store of iron is in the liver. Other metallic ions, especially copper, seem to be essential to hemoglobin formation, but they are needed in such small amounts that clinical deficiencies rarely, if ever, occur. Clinical experience indicates that thyroid, adrenal and certain pituitary secretions are essential for normal erythropoiesis.

Under ordinary circumstances the production of red blood cells is stimulated by reduced oxygen content of the blood, which may result from hemorrhage, hemolysis, cardiac or pulmonary disease, or the breathing of an atmosphere low in oxygen content. If the necessary elements for blood cell production are available in adequate amounts, chronic anoxia of marrow will lead to polycythemia. The manner in which anoxia stimulates erythropoiesis is unknown, but humoral factors play a role, inasmuch as anemic animals have in their plasma a substance which increases blood production in normal animals. This substance, erythropoietin, appears in increased amounts when there is hypoxia or anemia.

Erythropoietin contains cobalt, but anemia is not known to occur in man as a result of deficiency in this mineral. In large doses cobalt may stimulate polycythemia, but since it apparently does so only by interfering with transport of oxygen in marrow, its use as a therapeutic agent is unwarranted.

The mean number of red blood cells per cubic millimeter of blood varies with the age of the infant or child. Fetal blood is relatively rich in erythrocytes, which number between 5 and 7 million per cubic millimeter. There may be a transient increase during the first few hours after birth due to redistribution of plasma water and electrolytes, but there is a rapid fall to a lower level during the first week and a more gradual fall in the next three months to a level of about 4 million per cubic millimeter. There is a corresponding and somewhat greater fall in hemoglobin concentration. The fall in red blood cells and hemoglobin may be more pronounced in premature than in full term infants, owing to the proportionately greater demands of growth.

The erythrocytes of the newborn infant are somewhat larger than adult cells; they become smaller as they decrease in number. At three to six months of life the red blood cell measures 5 microns in diameter, in contrast to 8 microns at birth; by eight months the cells have attained the adult size of 7 microns.

During childhood the normal red blood cell count is below the standard for adults, ranging between 4 and 5 million cells per cubic millimeter, with correspondingly reduced hemoglobin levels. A hemoglobin level of 11.0 to 13.5 gm. per 100 ml. may be accepted as within the range of normal values

FIG. 301. Average blood values in infants and children. Note changes in size and in hemoglobin content of red blood cells producing microcytosis and hypochromia at ages of 3 to 3 1/2 months with gradual recovery thereafter.

Table 102. Average Normal Blood Values at Different Age Levels

	At Birth	At 2 Days	At 14 Days	At 3 Months	At 6 Months	At 1 Year	At 2 Years	At 4 Years	At 8-12 Years

\* Hemoglobin in whole blood: value of 15.6 gm. per 100 ml. equivalent to 100 per cent.

for children (corresponding to 70 to 90 per cent of the mean normal value for adult males).

The decrease in hemoglobin and red blood cell levels which characterizes the early part of the first year of life is sometimes referred to as "*physiologic anemia of the newborn*," and the accentuation of it in premature infants is referred to as the "*anemia of prematurity*." Neither condition is to be regarded as a morbid state, since both will ordinarily respond without treatment.

Iron is usually given to the premature infant at three to four weeks of age to compensate for depletion of fetal stores by rapid growth. Under exceptional circumstances, as when his erythropoietic function is depressed by infection, the premature infant may need to be assisted over a low point of anemia by transfusions of blood.

The normal red blood cell has a useful life of about 120 days. This period may be shortened to as much as a few days by such factors as exposure to hemagglutinins or hemolysins (erythroblastosis fetalis, favism, transfusion reaction, acquired hemolytic anemia) or abnormalities of shape or structure (hereditary spherocytosis, sickle cell disease, thalassemia).

At the end of its life span the normal erythrocyte probably undergoes intravascular

fragmentation and disintegration. The resulting particles, which contain hemoglobin, are phagocytized by reticuloendothelial tissue. Rapid dissolution of large numbers of red blood cells rarely occurs in the vascular system. When it does occur, the result may be hemoglobinemia and hemoglobinuria, since the human kidney handles hemoglobin inefficiently. Acute renal failure may be the result of severe intravascular hemolysis.

When dissolution of the erythrocyte particles occurs in reticuloendothelial tissue, the hemoglobin molecule is split into two fragments, the protein, globin, which enters the protein metabolic pool, and the heme prosthetic group, which is degraded to bilirubin and excreted by the liver. Iron freed in the process is reused in the formation of more hemoglobin.

Newly formed bilirubin bound to albumin and to alpha and beta globulins is carried in the plasma, where it gives the indirect bilirubin reaction. In the liver, bilirubin is conjugated with glucuronic acid to form a more soluble bilirubin glucuronide. In this form bilirubin is excreted into bile and enters the intestinal tract; there it is changed to urobilinogen, which appears in the feces or may be reabsorbed to be excreted in bile again or in the urine (see pp. 281, 695).

If the pathway for excretion of bilirubin is

blocked beyond the point where the bilirubin glucuronide is formed, this complex may be regurgitated into the blood stream, where it gives the direct bilirubin reaction. If no bile or bilirubin reaches the intestinal tract, no urobilinogen will appear in the feces or in urine.

When the destruction of blood takes place more rapidly than normal, the liver may be unable to excrete the increased load of bilirubin. Bilirubin accumulates in the plasma in the indirectly reacting form, and large amounts may also be excreted, in which case urobilinogen in stools and urine will be increased. Urinary urobilinogen may also be increased during normal hemolytic activity when hepatic function is deficient.

Thus, when there is excessive destruction of erythrocytes, there will be some degree of bilirubinemia, often with clinical jaundice and with large amounts of bile pigment in

the urine and stool, and there may be hemoglobinemia and hemoglobinuria. The spleen and to a less degree the liver may enlarge as a consequence of increased activity of their reticuloendothelial elements. Ordinarily there is responsive activity of erythropoietic tissue in marrow, and occasionally in other tissues, and rapid formation of new red blood cells is manifested by the appearance of relatively immature forms in the peripheral blood. Reticulocytes, normally about 1 to 2 per cent of circulating erythrocytes, may number as much as 30 to 35 per cent of the red blood cells, and normoblasts and even more immature forms may be found. Blood extravasated into body tissues is handled by the reticuloendothelial elements in the manner described, but only if the loss is massive do hyperbilirubinemia and jaundice appear. When the bleeding is external, these signs of increased hemolytic activity are not seen.

## THE ANEMIAS

Anemia is the most common disorder of the blood in children. The deficit of erythrocytes or of hemoglobin always reflects a disturbance of the dynamic balance between production and destruction or loss of these elements. The various anemias may be classified according to the primary disturbance (see Table 103).

**Table 103. Classification of the Anemias**

- I. Inadequate production of red blood cells or hemoglobin
  - A. Inadequate numbers of cell precursors in the marrow
    1. Congenital hypoplastic anemia
    2. Aplastic anemias
      - a. Congenital
      - b. Chemical and physical injury
      - c. Myelophthisis
    3. Hypothyroidism
  - B. Cellular marrow with depressed function
    1. Anemia of chronic infection
    2. Anemia of chronic azotemia
  - C. Cellular marrow with specific nutritional deficits
    1. Anemia due to a deficiency in antipernicious anemia factors (megaloblastic anemias)
    2. Anemia due to a deficiency of iron
- II. Excessive loss of red blood cells
  - A. Hemorrhage
    1. Acute
      - a. Acute hemorrhage in the newborn
    2. Chronic

### B. Hemolysis

1. Congenital abnormalities in erythrocytes or hemoglobin
  - a. Hereditary spherocytosis
  - b. Congenital nonspherocytic hemolytic anemia
  - c. Thalassemia
    - (1) Thalassemia minor
    - (2) Thalassemia major
  - d. Production of hemoglobin S
    - (1) Sick cell trait
    - (2) Sick cell disease
  - e. Production of hemoglobins C, D, E, G, H or I and others
    - (1) As traits (heterozygotes)
    - (2) As homozygotes
  - f. Double heterozygotes of abnormalities in synthesis of hemoglobin
2. Acquired abnormalities of the erythrocyte or its environment
  - a. Toxic hemolytic anemias
    - (1) Chemical poisons
    - (2) Drugs
    - (3) Bacterial toxins
  - b. Infections with parasitization of erythrocytes
    - (1) Malaria
    - (2) Oroya fever
  - c. Hemolytic anemia associated with burns
  - d. Hemolytic anemias due to immune reactions
    - (1) Acquired hemolytic anemia
    - (2) Paroxysmal cold hemoglobinuria
    - (3) Passive immune states
      - (a) Blood transfusion reactions
      - (b) Erythroblastosis fetalis

## *Anemias Due to Inadequate Production of Erythrocytes or Hemoglobin*

Anemias due to deficient production of erythrocytes and hemoglobin have certain features in common, whatever the fundamental defect. In these anemias the onset is insidious. Since only 0.8 per cent of the erythrocyte population of the body is lost each day, even sudden failure in cell production without increased losses will lead to anemia only as rapidly as normal cells are removed from circulation. Such evidence of excessive erythrocyte destruction as bilirubinemia, icterus, increased excretion of bile pigments, or splenomegaly will not be found. Since erythrocyte production is deficient in these anemias, erythroid hyperplasia of the marrow is not found, and there is no reticulocyte response to the demand for blood. Many of these anemias are resistant to therapy and carry a grave prognosis.

### **CONGENITAL HYPOPLASTIC ANEMIA**

(ERYTHROGENESIS IMPERFECTA)

Congenital hypoplastic anemia is characterized by an inability of the bone marrow to produce adequate numbers of erythrocytes. The anemia is not present at birth, but may be manifest as early as three weeks of age. The reduction in the level of hemoglobin does not usually become significant until two or three months of age. The course of the disease is variable, and the prognosis guarded. The patient is usually dependent for years upon frequent blood transfusions.

**Etiology.** The cause of the anemia is unknown; a familial occurrence is often found. Miller et al. have found a disturbance of the intermediary metabolism of tryptophane in six children, each of whom had an abnormal excretion of 3-hydroxykynureine and kynurenin, together with conjugation products of each compound. The relation between this metabolic disturbance and the failure of erythropoiesis is obscure.

**Clinical Manifestations.** These children display the pallor and inactivity associated with severe anemia. Cathie has observed a physical pattern of tow-colored hair, snub noses, a broad vermilion border to the upper lip, and wideset eyes. Growth and development are usually within normal limits, but stunting has been observed in severe cases. Splenomegaly, hepatomegaly, lymphadenopathy and icterus are absent, except as the

liver may become moderately enlarged as the result of hemosiderosis secondary to repeated transfusions. Since the production of leukocytes and platelets is normal, hemorrhagic phenomena and unusual susceptibility to infection are not part of this clinical pattern.

**Laboratory Data.** The diagnosis is established by demonstration of failure of production of erythrocytes with normal production of other formed elements. The red blood cell count may fall below one million per cubic millimeter. The hemoglobin level will be correspondingly reduced, since the anemia is normocytic and normochromic. The reticulocyte count does not exceed 2 per cent in spite of the severe anemia. The leukocyte count is normal, and the leukocytes respond normally to infections. The platelet count is normal. Erythrocyte fragility is normal, as are hemostasis, pigment metabolism and skeletal roentgenograms.

Examination of the bone marrow reveals a deficiency, usually severe, in the number of erythrocyte precursors. There may be a relatively normal number of early erythroid precursors with a distinct failure of maturation beyond the stage of the basophilic normoblast. The marrow contains few reticulocytes.

**Differential Diagnosis.** Congenital hypoplastic anemia is distinguished from hemolytic anemias of early infancy by the absence of splenomegaly, morphologic defects in the red blood cell, reticulocytosis or icterus. Mild or treated erythroblastosis fetalis may present a normocytic and normochromic anemia at seven to eight weeks of age, but at this time a reticulocytosis will usually be present, and further progression of anemia will not occur. The anemia of acute blood loss may be normochromic and normocytic, but there is also reticulocytosis, and the diagnosis is established when the site of loss of blood is demonstrable. Aplastic anemias are accompanied by leukopenia and thrombocytopenia.

**Course and Prognosis.** The disease is characterized by persistent and progressive anemia, and the prognosis is guarded. Spontaneous and complete recovery may occur at any age, but is more likely in the prepubertal period. Cardiac failure may lead to sudden death if the anemia becomes severe. Transfusion accidents and transfusion hemosidero-

FIG. 302. Congenital aplastic anemia with multiple anomalies (Fanconi syndrome) in a boy aged 4½ years. Pallor and inadequate growth and development were present from birth, but became exaggerated at 4 years, when bleeding manifestations appeared. Anomalies included bilateral absence of radii and thumbs, syndactylism, hypospadias, cryptorchism and horseshoe kidney. All formed elements of the blood were depressed. The bone marrow initially showed normoblastic hyperplasia, but subsequently there was increasing evidence of hypoplasia. Whole blood transfusions corrected the anemia temporarily. Iron, liver extract and folic acid administration, singly or combined, produced no response. Splenectomy was ineffective. Death occurred at the age of 5½ years.

sis are a constant threat to these children, who are entirely dependent upon transfusion for survival. With adequate care, however, growth and development of these children are normal, and many lead active, happy lives for many years. In persistent cases hypogonadism may be present in the postpubertal period.

**Treatment.** Transfusions with whole blood or preferably with sedimented erythrocytes should be given as often as necessary to maintain the hemoglobin level at 6 gm. per 100 ml. (40 per cent of normal) or above. Cardiorespiratory embarrassment and frank cardiac failure may occur if the hemoglobin level falls below this point.

Diathermy over the sternum and long bones has been reported to produce a temporary erythropoietic response. It may be repeated, if effective, as often as necessary to maintain blood levels above those necessitating transfusion. In younger patients especially, corticosteroids are efficacious in stimulating the bone marrow to an increased production of reticulocytes with a subsequent increase in peripheral levels of erythrocytes and hemoglobin. Several infants have maintained normal erythrocyte and hemoglobin levels during continuous therapy with small doses of these steroids. Splenectomy has not been of benefit, nor has administration of iron, folic acid, vitamin B<sub>12</sub>, cobalt or other blood nutrients.

## THE APLASTIC ANEMIAS

Aplastic anemia cannot be regarded as a specific clinical entity. Characteristically, failures in granulocyte and platelet production accompany the deficit in erythrocyte formation. The anemia is likely, therefore, to be accompanied by infections and bleeding. The types of aplastic anemia may be classified according to etiology as follows:

- I. Aplastic anemia of genetic origin
  - A. Congenital aplastic anemia (Fanconi)
- II. Aplastic anemias due to chemical and physical agents
  - A. Drugs and industrial and household chemicals
  - B. Radiation injury
- III. Aplastic anemias due to infection
- IV. Myelophthisic aplastic anemias
- V. Aplastic anemias of unknown cause
  - A. Idiopathic aplastic anemias
  - B. Preleukemic states.

### Congenital Aplastic Anemia (Fanconi).

In 1927 Fanconi reported the occurrence of aplastic anemia in association with multiple congenital anomalies in three male siblings. These children had hyperpigmentation, microcephaly, hypogonadism, exaggerated tendon reflexes and congenital strabismus. In other reported instances there have been anomalies of the heart and genitourinary tract and, most consistently, defects of the bones of the

radial sides of the forearm and hand. Cleft palate has also been noted.

Erythropoietic failure may be evident shortly after birth or be delayed for variable periods of time. It is manifest by thrombocytopenia, granulocytopenia and/or anemia and by the associated symptoms of bleeding, infection or distress due to anemia. Treatment is limited to the use of antibiotic drugs and to transfusions of whole blood. Corticotropin and cortisone are of no value. Few patients survive the early years of childhood.

**Aplastic Anemias Due to Drugs and Other Chemical Agents.** Aplastic anemia most commonly results from the toxic action of chemical substances on the bone marrow; these substances include a wide variety of drugs and industrial and household chemicals. Among the drugs are organic arsenicals, bismuth, mercury, the sulfonamides, chloramphenicol, the hydantoins and streptomycin. The main offenders among the chemical agents are paints, lacquers, paint removers, cleaning solutions, gasoline, hydrocarbons which contain crude benzene, and insecticides containing halogenated hydrocarbons. These highly volatile substances may be absorbed through the lungs in poorly ventilated rooms or inhaled directly from such containers as gasoline tanks. There is great individual variation in the degrees of susceptibility to these agents; children are more susceptible than adults.

Many weeks may elapse after exposure to a toxic agent before the resulting aplastic anemia makes its clinical appearance. Hemorrhagic and infectious symptoms may precede the onset of severe, progressive anemia, and usually dominate the clinical picture. Extensive ulcerating and necrotizing infections of the mouth and pharynx and at times of the vagina and rectum are common. Platelet deficiency leads to spontaneous bleeding from the mucous membranes and to the development of extensive ecchymosis from minimal trauma. Recurrent epistaxis and vaginal bleeding may occur and be difficult to control. Intracranial hemorrhage is the most common cause of death.

In some instances exposure to benzene or benzene-containing compounds may be followed by rapid hemolysis. In such cases a hemolytic type of anemia with associated splenomegaly, hyperbilirubinemia and icterus precedes the toxic effect on the bone marrow.

**Aplastic Anemia Due to Radiation Injury** (see also Radiation Injury). Small doses of roentgen rays stimulate granulopoiesis, but

overexposure may lead to aplastic anemia in children. Lymphocytes are the most susceptible of the blood elements to the effects of radiation; granulocytes and platelets are somewhat more resistant, and erythrocyte precursors are the least susceptible. Accordingly, the clinical pattern in radiation anemia is likely to be dominated by infection and hemorrhage.

**Aplastic Anemia Due to Infection.** Only in the newborn period have we encountered aplasia of the marrow as a result of infection. Thrombocytopenia and agranulocytosis do not occur with anemia of chronic infection in the older child. In the newborn infant congenital syphilis, cytomegalic inclusion disease, toxoplasmosis and torulosis have been associated with aplastic anemia, and petechiae and purpura may be present at birth. Anemia is generally not a major clinical feature at the time of birth, but may be rapidly progressive during subsequent weeks.

**Myelophthistic Aplastic Anemia.** Aplastic anemia resulting from invasion or replacement of the medullary cavity of the long and membranous bones by nonhematopoietic tissue is rare in children. It may be caused by leukemia, osteopetrosis (Albers-Schoenberg disease), myelofibrosis, Letterer-Siwe disease and Gaucher's disease.

**Aplastic Anemias of Unknown Cause.** Only after the most careful search for the cause of aplastic anemia may one regard the condition as "idiopathic." Many of the apparently idiopathic cases are subsequently found to be leukemia, and of the remaining ones many are probably due to unrecognized contacts with chemical or physical agents.

**Laboratory Data in Aplastic Anemias.** The anemia is usually a normocytic, normochromic one, but occasionally macrocytes may be seen. Although the total leukocyte count may be near the normal level, the number of granulocytes is generally reduced and may be for days or weeks before a significant anemia occurs. The platelet count is low early in the course of the disease and may persist at levels of 20,000 to 40,000 per cubic millimeter for prolonged periods of time. Reticulocytes are decreased in number.

Except when a hemolytic process is associated with an aplastic anemia at its onset, blood bilirubin levels are normal, and other blood chemical studies are noncontributory. Roentgenograms of the long bones may indicate the primary process in the rare instances of myelophthistic anemia.

The bone marrow consists largely of fatty and fibrous tissue with only small clusters of hematopoietic cells; except in myelophthistic aplastic anemia, when it may disclose the invasive process. If aspiration biopsy reveals only an inadequate amount of functional tissue or if the findings are equivocal, a generous sample of marrow should be removed surgically from the sternum to ensure an adequate specimen and to avoid contamination with peripheral blood.

**Differential Diagnosis.** In *anemias due to nutritional deficiencies* granulopenia and thrombocytopenia are not so marked as in aplastic anemias, and the bone marrow reveals normal or greater than normal cellularity. When *idiopathic thrombocytopenic purpura* is accompanied by anemia due to blood loss, the clinical pattern may suggest aplastic anemia, but a leukocytosis is to be expected, and a reticulocytosis will occur in response to the blood loss. *Secondary hypersplenism* may resemble aplastic anemia, since the peripheral blood may have low levels of those formed elements produced in marrow. In hypersplenism, however, the low levels are the result of excessive destruction of cells, not of inadequate production; the marrow is hypercellular, and there is a reticulocytosis in the peripheral blood. The rare aplastic crises of certain *hemolytic anemias* may be differentiated from aplastic anemia by the transitoriness of the aplastic process and by identification of abnormal erythrocytes characteristic of the hemolytic anemia, such as spherocytes or sickle cells.

**Course and Prognosis.** The course of aplastic anemias in childhood is usually chronic, only temporary relief being obtained from transfusions. Infections are difficult to control, and a tendency to ready bleeding is constantly present.

The prognosis is guarded; recovery or death may occur after months of illness. Cerebral hemorrhage is a common terminal event. The likelihood of recovery depends in large part on the etiologic factor; about half of the children with toxic aplastic anemias will survive with adequate care.

**Treatment.** In most instances treatment is limited to the use of antibacterial agents and to blood transfusions. It is desirable to maintain the hemoglobin level at 7.5 gm. per 100 ml. (50 per cent of normal) or above.

Transfusion of citrated whole blood from glass containers is not effective for the control of hemorrhage or infections, since most of the granulocytes and platelets are destroyed.

If, however, plastic containers and apparatus made nonwetttable by silicone films are used, clinically effective numbers of platelets and possibly of leukocytes can be transfused in fresh blood. The life span of such cellular elements is short, and benefit is of only a few days' duration at most. Striking benefit may result from the transfusion of platelet-rich blood from polycythemic donors. Transfusion of platelet-rich plasma through properly prepared nonwetttable apparatus may also be helpful.

Cortisone and ACTH have not been consistently beneficial in the aplastic anemias produced by toxic agents. Cortisone and prednisone seem to be somewhat more effective than ACTH and may be helpful in relatively large doses early in the course of the disease.

Administration of the various substances necessary for hematopoiesis in larger than normally required quantities is not effective in stimulating the aplastic marrow. Splenectomy is a dangerous procedure.

Anti-infectious prophylaxis with antibiotics and sulfonamides is an important adjunct, but the use of these agents is not without danger, since resistant pathogens may become established. Even the most minor infections are threatening and should be treated promptly with the guidance of adequate bacteriologic diagnosis.

## ANEMIA OF CHRONIC INFECTION

The anemia of chronic infection is a normocytic, normochromic anemia of moderate severity which develops over a long period of time. Erythropoiesis is depressed, and there is no response to the nutrient substances essential for formation of erythrocytes and hemoglobin so long as the infection is active. With advances in therapy of infectious diseases, this type of anemia has become uncommon and accounts for less than 2 per cent of anemias as seen in children in the United States. Severe hemolytic anemias are occasional manifestations of acute infections, but they bear no relation to the anemia of chronic infection.

**Pathogenesis.** The anemia of chronic infection results from an inability of the marrow to incorporate iron into the protoporphyrin molecule. The resulting disturbances in synthesis of heme and of hemoglobin are not related to deficiency of iron and are not corrected by administration of it. Ingested iron is absorbed normally, but disappears

rapidly from the plasma; both the serum iron level and the serum iron-binding capacity are low. The free protoporphyrin of the erythrocytes and the levels of urinary coproporphyrin and blood copper are consistently increased.

**Clinical Manifestations.** The only sign specifically related to the anemia is mild pallor. The anemia is never so severe as to cause symptoms of cardiorespiratory distress; these and other symptoms or signs, such as hepatosplenomegaly or icterus, if present, are related to the infectious process.

**Laboratory Data.** The hemoglobin level is usually in the range of 8.5 to 11.0 gm. per 100 ml., with a proportionate reduction of the red blood cell count. The erythrocytes are often slightly smaller than normal, but slight macrocytosis also may be occasionally observed. Hypochromia is unusual except after prolonged infections. The extent of the anemia may not be accurately reflected by the findings in the peripheral blood, since the blood volume may be as low as 60 to 70 per cent of the normal value. The reticulocyte count is low; the platelet count is normal, and the leukocyte count is consistent with the infection, granulocytes being produced in adequate numbers.

The cellularity of the bone marrow is normal or increased. Hyperplasia, if present, involves principally the myeloid (granulopoietic) elements.

**Differential Diagnosis.** The anemia of chronic infection is differentiated from acute hemolytic anemias by the absence of clinical and laboratory signs of blood destruction. If there are disturbances in the production of white blood cells and platelets, aplastic anemia rather than the anemia of chronic infection is suggested.

**Course and Prognosis.** If the infection is brought under control, the anemia will be gradually corrected within several weeks. The anemia is rarely severe enough to modify seriously the course of the infection.

**Treatment.** Treatment is that of the primary infection. The effect of transfusions is temporary and rarely justifies the expense and danger which accompany them. Administration of supplementary amounts of the nutrients essential for erythropoiesis has no advantage over a well balanced diet. Cobalt chloride results in the formation of erythrocytes and hemoglobin even in the presence of infection, but no symptomatic improvement has been observed, and it is felt to be contraindicated.

## ANEMIA OF CHRONIC AZOTEMIA

This anemia, which is normocytic and normochromic, develops in patients with chronic azotemia of renal or extrarenal origin. Generally it results from inadequate production of red blood cells, but infrequently there may be a hemolytic factor if the azotemia is severe. At such times the anemia may be sudden in onset and progress rapidly. The mechanism responsible for the anemia in azotemia is not known.

The clinical findings are those of the illness responsible for the azotemia, except as the anemia is severe, when it may contribute to cardiac failure. Occasionally azotemic anemia is the first manifestation of serious renal or metabolic disease not otherwise recognized.

**Laboratory Data.** The severity of the anemia is proportionate to the degree of nitrogen retention; in extreme cases hemoglobin levels may be as low as 4 to 5 gm. per 100 ml. The erythrocyte count and hematocrit value are proportionate to the hemoglobin level, since the anemia is ordinarily normochromic and normocytic. In unusually persistent cases a mild degree of microcytosis may be found. The reticulocyte count is low, except as there may be a hemolytic component contributing to the anemia. Leukocytes are increased in number, with a preponderance of granulocytes. The platelet count is normal. The bone marrow is usually hypercellular, with the increase in cells confined to the myeloid elements.

**Course and Prognosis.** These depend upon the primary disturbance.

**Treatment.** As a rule no specific treatment is needed for the anemia. Blood transfusion is not indicated except when the hemoglobin level is very low. The usual nutrient substances necessary for hematopoiesis have no effect. Cobalt chloride may lead to elevation of erythrocyte and hemoglobin levels, but clinical benefit is doubtful and toxic reactions are common; such therapy is rarely indicated.

## THE MEGALOBlastic ANEMIAS

In the absence of certain nucleic acids the normal maturation of erythrocyte precursors in marrow is interrupted. These necessary substances include ascorbic acid, vitamin B<sub>12</sub>, folic acid and certain purines and pyrimidines (thymine and thymidine). Deficits of these substances lead to cytologic alterations in erythrocytes and erythrocyte precursors which are characteristic of megaloblastic

anemias (pernicious anemia-like anemias). The erythrocytes are macrocytic and hyperchromic. Since granulocyte and platelet precursors also share the need for these nutrients, various degrees of granulocytopenia and thrombocytopenia accompany megaloblastic anemias.

Those occurring in infants and children may be classified as follows:

- I. Juvenile pernicious anemia
- II. Megaloblastic anemia of infancy
- III. Megaloblastic anemias of intestinal origin
  - A. Celiac disease
  - B. Cystic fibrosis of the pancreas
  - C. Congenital strictures
  - D. Surgical shunts
  - E. Intestinal infections and infestation
- IV. Megaloblastic anemias of metabolic origin
  - A. Chronic liver disease
  - B. Rare instances of acute leukemia
- V. Others
  - A. With phenytoin sodium therapy
  - B. With chronic hypoparathyroidism

#### JUVENILE PERNICIOUS ANEMIA

In pernicious anemia, which is rare in children, vitamin B<sub>12</sub> is not absorbed from the gastrointestinal tract, owing to a lack of the intrinsic factor in the gastric secretion. The deficiency which results leads to a megaloblastic anemia and to degenerative lesions in the central nervous system. The reason for deficiency of the intrinsic factor is unknown; a genetic factor is a possibility.

**Clinical Manifestations.** The observed age of onset has ranged from four months to fourteen years. The presenting symptoms are usually pallor and easy fatigability. Atrophy of the papillae of the tongue and recurrent glossitis have been consistently found. Neurologic manifestations are more likely to occur in children with prolonged illnesses and include ataxia, paresthesias and absence of tendon reflexes. Clinical jaundice has not been noted, nor is there splenomegaly or lymphadenopathy.

**Laboratory Data.** A severe anemia is usually present, with hemoglobin levels often below 4 to 5 gm. per 100 ml. Since the anemia is macrocytic, the erythrocyte count will be relatively lower than the hemoglobin level or hematocrit value. The mean corpuscular volume may be as high as 130 cubic microns. The reticulocyte count is low prior to therapy. The total leukocyte count is low with neutropenia and a relative lymphocytosis. The platelet count is reduced, but not to levels at which spontaneous bleeding is likely to occur.

The bone marrow is characterized by mega-

loblastic erythropoiesis, with failure of maturation of erythroid elements. The abnormal granulocytic elements seen in adults with pernicious anemia have been found in juvenile cases and consist of giant metamyelocytes, hypersegmented polymorphonuclear leukocytes and atypical mitotic figures.

Blood chemical studies give essentially normal results; the evidences of a hemolytic process which may be found in adults have not been prominent in children. The intrinsic factor is absent in gastric secretion. A histamine-resistant achlorhydria is not always present.

The *diagnosis* of pernicious anemia can be considered only when there is a megaloblastic marrow in association with the absence of the intrinsic factor in the gastric secretion and a continuous need for parenteral therapy with vitamin B<sub>12</sub>.

**Course and Prognosis.** Remissions occur promptly with specific therapy. Relapses should not occur with a well planned program. Death from untreated pernicious anemia or during a severe relapse may be due to infection, to cardiac failure or to overzealous transfusion therapy.

**Treatment.** Parenteral administration of crystalline vitamin B<sub>12</sub> or liver extract containing vitamin B<sub>12</sub> is specific. The recommended dose for initial therapy or for relapses is 15 micrograms, given intramuscularly, every day or two for one to three weeks. The same dose is then given every two to four weeks, according to apparent need. Oral administration is optimally effective only if normal gastric juice is also given to supply the intrinsic factor.

Folic acid, given orally, usually produces a temporary and incomplete hematologic response, but has no effect upon the neurologic manifestations. Iron may be needed by the young patient who has had a diet deficient in iron. A transfusion of blood is rarely necessary.

#### MEGALOBlastic ANEMIA OF INFANCY

Megaloblastic anemia of infancy occurs most commonly in infants of five to eleven months of age and appears to be the result of a relative deficiency of folic acid. The exact pathogenesis is not understood, but it is thought that persistent mild infections may increase the need for folic acid to such an extent that it cannot be met without dietary supplementation. The anemia has been observed especially in infants with deficient intakes of ascorbic acid and in prematurely born ones.

There are no characteristic clinical signs. The spleen may be enlarged.

Complete recovery is to be expected with specific therapy in three to four weeks. Continuation of therapy after recovery is not necessary as it is in pernicious anemia. Untreated, the course is progressive, and severe gastrointestinal and respiratory infections are common terminal events.

**Laboratory Data.** The erythrocyte count is significantly reduced and may be less than one million per cubic millimeter. Hemoglobin and hematocrit levels are low, but not in proportion to the red blood cell count. The erythrocytes are usually macrocytic and hyperchromic. Occasionally they are normocytic; and only examination of marrow will reveal the nature of the anemia. The reticulocyte count is low, and the platelets and granulocytes are reduced in number. The nuclei of the polymorphonuclear leukocytes tend to be hypersegmented.

The bone marrow reveals megaloblastic erythropoiesis, with an arrest in maturation at an early level. Relatively few mature normoblasts are present. Atypical mitotic figures and giant metamyelocytes are found among the myeloid elements. Platelet production is depressed, and there may be a relative increase in mature megakaryocytes. The changes in marrow may vary considerably in degree.

**Treatment.** Folic acid corrects the nutritional deficiency. It is given orally in three or four divided doses, totaling 15 to 20 mg. each day. After two or three weeks the dose can be reduced to 5 mg. daily. The duration of therapy should be adjusted according to the severity of the anemia and the persistence of infection.

Vitamin B<sub>12</sub> is not effective, and ascorbic acid has no effect in the absence of folic acid. Unless there is associated iron deficiency, there is no need for therapeutic iron. Transfusion is not needed, except when the erythrocyte count is extremely low. Appropriate antibiotic agents should be administered for concurrent infections.

#### MEGALOBlastic ANEMIA OF INTESTINAL ORIGIN

Megaloblastic anemia resulting from defective intestinal absorption of antipernicious anemia factors is rare in children. It may occur in association with idiopathic steatorrhea (celiac disease), with fibrocystic disease of the pancreas, and with a variety of anomalies and surgical conditions of the gastrointestinal tract. The studies of Watson and

Witts indicate that megaloblastic anemia associated with anomalies or surgical lesions of the gastrointestinal tract may arise from stagnation and changes in bacterial flora rather than from absorptive losses. The main deficiency appears to be that of vitamin B<sub>12</sub>, but deficiencies of folic acid or closely related substances may occur independently or coexist.

The *clinical picture* is usually dominated by the manifestations of the intestinal disturbance. Lingual atrophy, glossitis and neurologic disturbances may occur if the course is prolonged.

The anemia is normochromic, usually macrocytic, and some anisocytosis is commonly present. The leukocyte count is low, and there is a moderate reduction in the number of platelets. Examination of the marrow reveals hyperplasia of erythroid elements, with a predominance of megaloblasts. The myeloid cells and megakaryocytes show changes similar to those in pernicious anemia. Serum bilirubin levels are ordinarily normal, and the intrinsic factor is usually present in the gastric juice.

The course of the anemia is slowly progressive without treatment. There is a prompt response to replacement therapy or to correction of the intestinal abnormality.

**Treatment.** This should be directed at the intestinal abnormality whenever possible. In addition, specific replacement therapy in the form of liver extract, which supplies vitamin B<sub>12</sub> and other factors related to folic acid, is given daily for one to two weeks in doses of 15 units intramuscularly. The need for further therapy will depend on continuation of the gastrointestinal defect.

#### MEGALOBlastic ANEMIA ASSOCIATED WITH OTHER DISTURBANCES

Severe chronic disease of the liver may occasionally be responsible for megaloblastic anemia. In acute leukemia the rapid growth of leukemic tissue may create an excessive demand for folic acid or related substances; in addition, the relative deficiency of these substances may be accentuated by treatment with folic acid antagonists. Under these circumstances megaloblastic erythropoiesis may be found in the marrow and marked macrocytosis in the peripheral blood.

Megaloblastic anemia occasionally develops in patients receiving prolonged anticonvulsant therapy, particularly with phenytoin sodium. This anemia responds to folic acid, but not to vitamin B<sub>12</sub>. A megaloblastic ane-

FIG. 303. A, Peripheral blood smear of an infant with *anemia due to iron deficiency* of nutritional origin. The erythrocytes are small and pale and vary greatly in size and shape. B, Peripheral blood smear of an infant with *megaloblastic anemia of infancy*. The erythrocytes vary in size, some being almost as large as neighboring leukocytes, but their shape is well preserved, and they are well filled with hemoglobin. The nuclei of the neutrophils are characteristically multilobate.

mia responding to parenteral administration of vitamin B<sub>12</sub> has also been described in several patients with chronic hypoparathyroidism and moniliasis.

### ANEMIA OF IRON DEFICIENCY

A deficiency of iron is the most common cause of anemia and the most common nutritional deficiency in children in the United States. Either inadequate intake or excessive loss of iron will lead to iron deficiency. The erythrocytes will be small (microcytic) and poorly filled with hemoglobin (hypochromic).

**Etiology.** During the first six months of life the infant is dependent principally upon the adequacy of his storage of iron from late prenatal life for protection against iron deficiency. Iron stores may be inadequate if the mother has been depleted of iron by excessive losses of blood, poor diet or multiple pregnancies. If the infant is born prematurely, the relatively low stores of iron from a shortened pregnancy may be inadequate for the requirements of rapid growth. If the infant is one of twins, he must share maternal iron. Since these causative factors are relatively infrequent, the incidence of iron deficiency anemia is low in the first six months of life.

After the first six months the infant is dependent upon a continuing exogenous source of iron. The incidence of iron deficiency is highest in infants between nine and twenty-four months of age; it drops rapidly there-

after, and iron deficiency due to inadequate intake is relatively rare after three years of age. Subsequently chronic hemorrhage is the principal etiologic factor. Poorly planned meals, feeding problems and behavior disturbances often result in diets made up largely of milk, bread and other foods mainly carbohydrate in content. Absorptive defects as in chronic diarrhea, steatorrhea, gastrointestinal anomalies or colitis may also lead to iron deficiency.

Owing to the limited capacity for absorption of iron even when the demand is increased, iron deficiency of some degree results from acute and chronic hemorrhages. Hemorrhage less commonly causes hypochromic anemia in children (p. 943) than in adults; in the southern United States chronic blood loss associated with hookworm infestation leads to iron deficiency anemia.

**Clinical Manifestations.** The four common manifestations of iron deficiency anemia are pallor, irritability, anorexia and decrease in normal activity. Anorexia leads to a vicious cycle, in which the deficiency of iron is accentuated by an inadequate dietary intake. Anorexia is not due to the anemia itself, since it is not characteristic of anemia from other causes, and since it may disappear, after administration of iron intravenously, *before* an increase in hemoglobin level can be detected. Pica is not uncommon and often disappears with correction of the deficient diet.

Height and weight are usually within normal limits; obesity is more common than underweight. Pallor is usually evident, and mild to moderate degrees of periorbital or dependent edema may be present. The spleen may be moderately enlarged, particularly when there is an associated mild infection. Soft, blowing, apical systolic murmurs may be heard frequently, but cardiac enlargement is unusual. Though glossitis, koilonychia, loss of cutaneous elasticity and changes in texture of hair are common in adults with iron deficiency, they are rare in children.

**Laboratory Data.** The number of erythrocytes in the blood may be normal or slightly less than normal, but the hemoglobin level is always reduced and may be very low. The hematocrit value is also reduced. The red blood cells as seen in blood films are small and pale, with variations in size and shape (anisocytosis and poikilocytosis). In severe iron deficiency there may be an increase in resistance of a small portion of the erythrocytes to hemolysis in hypotonic saline solution. The reticulocyte count is low, even when the anemia is severe. The leukocytes, including the lymphocytes, show no significant change except as their number may be elevated in response to a concurrent infection. The platelet count is normal.

The serum iron level is lower than normal, and the serum level of iron-binding protein is above normal. The blood copper level and the level of free protoporphyrin in the erythrocytes are elevated. Hypoproteinemia is relatively common. Other blood chemical constituents are not significantly altered.

The bone marrow is characterized by hyperplasia of the late normoblastic elements with inadequate hemoglobin in their cytoplasm. Leukocyte and platelet elements and their precursors are not altered.

**Diagnosis.** The anemia of iron deficiency is not likely to be confused with other anemias. It may rarely coexist with megaloblastic anemia of infancy. The small, pale poikilocyte in stained smears of peripheral blood is evidence of iron deficiency, and the diagnosis should not be made in its absence. *Thalassemia* may occasionally be confused with iron deficiency anemia, but there will be evidence of hemolysis and of hyperactivity of marrow in respect to early erythroblastic as well as normoblastic elements.

**Course and Prognosis.** Untreated iron deficiency anemia is slowly progressive. If it becomes unusually severe, cardiorespiratory distress or cardiac failure may occur. The

anemia responds promptly to adequate therapy; a moderate reticulocytosis occurs in four to seven days, followed by a gradual rise in the hemoglobin level. The ultimate prognosis depends in part upon the primary cause of the iron deficiency.

**Treatment.** It must be established whether the deficiency of iron is the result of inadequate dietary intake, absorptive defects or excessive losses. Supplementation of diet with medicinal iron will be ineffective unless all causative defects are corrected.

Since iron deficiency often grows out of faulty feeding habits, education of the parents is frequently indicated. In children with behavior disturbances this may be as difficult as it is essential. A large part of the caloric needs of the child must be supplied by foods rich in iron. Potatoes, spaghetti, bread, cookies and crackers should not be given until a well balanced diet is acceptable to the child. Milk should be limited to one pint a day. In exceptional instances when the mother is unable to effect a change in the child's dietary habits it may be expedient or necessary to carry out the dietary education of the child in the hospital through the sympathetic but firm efforts of nursing personnel.

Ferrous iron is more efficiently absorbed than the ferric salt. The daily intake should be in the range of 0.4 to 0.8 gm. of ferrous sulfate, which is equivalent to 100 to 200 mg. of elemental iron. Since only a small percentage of ingested iron is absorbed, the daily dose is given in at least two or three divided doses; this also reduces the incidence of gastrointestinal complaints. The tendency to discoloration of the teeth by iron can be minimized by taking liquid preparations through a tube and by brushing the teeth after the medication has been given. The discoloration is not permanent.

Owing to the ability of phosphorus-containing phytates and of phosphates to form insoluble salts with iron, medicinal iron should be given when the upper gastrointestinal tract is relatively free of these materials. Milk and milk products contain large amounts of phosphates, and cereals have a high content of phytates. Iron is therefore best given between meals. Colloidal preparations of iron for intravenous use and an iron-dextran mixture for intramuscular use are available. They are rarely indicated, however, and may lead to severe toxic reactions. They are specifically indicated only when there is a disturbance of gastrointestinal absorption and when correction of it is not immediately pos-

sible. They may also be helpful initially in the anemia of hookworm disease (see p. 583).

Transfusion of blood is rarely indicated. If cardiorespiratory distress, cardiac failure or

some other condition warrants transfusion in a severely anemic child, it should be carried out with caution, since the ischemic myocardium has a low tolerance for rapid increases in blood volume.

### *Anemias Due to Excessive Loss of Erythrocytes*

Erythrocytes may be lost by hemorrhage and by hemolysis. Anemias due to excessive loss of erythrocytes, in contrast to those due to failures of erythrocyte production, may be sudden in onset and are generally accompanied by a hyperactivity of the marrow. The severity of the anemia depends upon the ability to respond with increased erythropoietic activity.

#### **ANEMIA DUE TO ACUTE HEMORRHAGE**

The severity of the anemia will depend upon the extent of the blood loss and the rapidity with which it occurred. The anemia is normocytic and normochromic except as it occurs in a person with a pre-existing anemia of another type.

**Clinical Manifestations.** Although the clinical picture is often dominated by manifestations related to the cause of the hemorrhage, certain symptoms are independent of it. These are prostration, restlessness, thirst, rapid and thready pulse, and hypotension. Symptoms of shock may develop only after the child has assumed an erect position. By contrast, *bradycardia* often accompanies large losses of blood in patients who remain at rest. In adults the rapid loss of one third of the blood volume may result in death. Up to half of the volume, however, may be lost over a twenty-four hour period without necessarily a fatal outcome. When bleeding occurs into body cavities or tissues, resolution of the localized accumulation by hemolysis may result in icterus within two to five days.

**Laboratory Data.** Shortly after the sudden loss of blood there is a rise in the platelet count and a shortening of the coagulation time. Within two to five hours a polymorphonuclear leukocytosis appears which may persist for three to five days. Early changes in the hematocrit value may be misleading, since they are modified by redistribution of body fluids and by adjustments of plasma volume which may require several days. In general, there is a gradual fall in the hemoglobin level which does not necessarily indicate further loss of blood. The erythrocytes are normochromic; a hypochromic anemia with acute

loss of blood suggests previous hemorrhage or a nutritional deficiency of iron.

Within a few days regeneration of erythrocytes will be indicated by polychromatophilia, slight macrocytosis and reticulocytosis in the peripheral blood. The marrow will show an increase in the number of erythrocyte precursors and increased activity in the formation of myeloid elements.

After two to four days the serum bilirubin level may be slightly elevated in internal hemorrhage. Other blood chemical constituents are unchanged or will depend upon the cause of the loss of blood.

**Course and Prognosis.** The ultimate outlook depends upon the control of shock and prevention of further loss of blood and upon the primary morbid process. An isolated loss of blood in an otherwise healthy child will be corrected gradually over a period of five to seven weeks; the time required is not closely related to the amount lost.

**Treatment.** The immediate treatment is directed at control of the hemorrhage and shock. Transfusion of whole blood or plasma expanders may be urgently needed for restoration of blood volume. The well nourished child requires no further treatment following an isolated loss of blood other than a well balanced diet. Infants should receive supplemental iron for at least eight to ten weeks.

#### **ANEMIA DUE TO ACUTE HEMORRHAGE IN THE NEWBORN INFANT**

Acute hemorrhage may occur from the infant immediately before, during or just after birth. It may be evident externally when due to placental abnormalities, or it may be occult when it is from the fetus into the maternal circulation. In the latter situation, if the fetal blood is incompatible with the mother's, she may have a transfusion reaction. When vascular anomalies occur in the placenta of twins, bleeding from one twin to the other may lead to severe anemia in the "donor" twin. In infants delivered by cesarean section blood may be lost by poorly timed interruption of the umbilical cord or by accidental incision or rupture of the placenta.

Because the newborn infant has a small

blood volume, the loss of relatively small quantities of blood is often highly significant. The shock and anemia which result present urgent difficulties which must be differentiated from those presented by anoxia or hemolytic disease or other causes of anemia in the immediate newborn period.

The infant may be listless, limp and pale at birth, or he may rapidly become so after delivery. The fall in the hemoglobin level may be extremely rapid and may be apparent within an hour. The need for transfusion may be much more urgent than is suggested by the immediate clinical condition. An amount of blood equal to 10 per cent of the infant's estimated blood volume may be necessary immediately, and subsequently over a period of some hours as much as one quarter to one third of the infant's estimated normal blood volume may require replacement.

### ANEMIA DUE TO CHRONIC HEMORRHAGE

Losses of small amounts of blood over a long time lead to an anemia more severe than would be expected from the amount of blood lost. The unexpected severity results from a depletion of body iron. In the first few years of life anemia of iron deficiency is relatively common, most of the cases being due to dietary deficiency of iron. In later childhood hypochromic anemia is relatively infrequent in the United States, most cases being accounted for by chronic loss of blood.

**Etiology.** The gastrointestinal tract is the most common site of chronic hemorrhage, with bleeding from parasitic infestation, particularly hookworm disease, erosions associated with anomalies and polyps, defects in hemostasis, esophageal varices in association with congestive splenomegaly and ulcerative lesions. Recurrent epistaxes, hemorrhage into the lungs in idiopathic pulmonary hemosiderosis, and bleeding from tumors or ulcerations of the genitourinary tract are additional examples of infrequent causes of persistent hemorrhage.

**Clinical Manifestations and Laboratory Data.** The findings are those of iron deficiency anemia. Additional clinical features may point to the primary cause, and careful investigation, as for example repeated examinations of stools for occult blood, will usually disclose the site of hemorrhage. When there is doubt whether an anemia is of nutritional or chronic hemorrhagic origin, it may be expedient to carry out a short trial with an optimal diet and supplemental iron.

*Treatment* is directed primarily at the source of bleeding. Supplemental iron is also given orally as in other iron deficiency anemias. Transfusion of blood is not ordinarily needed except on occasion in patients requiring operation for correction of the defect responsible for loss of blood.

### HEMOLYTIC ANEMIAS

The hemolytic anemias of infancy and childhood can be separated into those resulting from congenital defects in the production of erythrocytes and/or hemoglobin and those dependent upon acquired defects in red blood cells or in their environment. A general classification is given in Table 103 (p. 933). These anemias have certain features in common. The spleen is a main site of the destruction of blood and is usually enlarged. An excess of bilirubin is formed from the heme of the destroyed cells which frequently leads to an elevation in serum bilirubin level and occasionally to clinical icterus.

In the peripheral blood active regeneration is evidenced by reticulocytosis and polychromatophilia. The marrow is the site of pronounced erythroid hyperplasia, which often leads to widening of the marrow spaces in long and flat bones, with the development of characteristic clinical and roentgenographic skeletal changes.

In severe chronic hemolytic anemias there may be a marked accumulation of iron-containing pigment in body tissues (hemosiderosis), which may be augmented by extensive transfusion therapy. Hemosiderosis may lead to hepatic enlargement and to a distinctive gray-green discoloration of the skin.

### HEREDITARY SPHEROCYTOSIS

(CONGENITAL HEMOLYTIC ANEMIA,  
FAMILIAL ACHOLURIC JAUNDICE,  
CONGENITAL MICROSPHEROCYTOSIS)

Hereditary spherocytosis is characterized by excessive destruction of abnormally shaped cells (spheroidocytes). The defect is inherited as a dominant character. This hemolytic anemia has been most commonly recognized in young adults, but careful study will lead to its recognition in infancy and early childhood.

Recent studies have demonstrated abnormalities in carbohydrate metabolism within the red blood cells of patients with hereditary spherocytosis. The number of energy-rich phosphate bonds in these cells is less than normal, with the apparent result that the cells

are unable to maintain a normal biconcave shape against the osmotic pressure of normal plasma.

The spleen is the principal site of entrapment, stagnation and excessive destruction of the abnormal, spherical erythrocytes. Removal of the spleen generally modifies the intensity of the hemolytic process significantly. It is not known what brings about hemolytic crises in hereditary spherocytosis.

**Clinical Manifestations.** Clinically apparent hereditary spherocytosis in early infancy is ordinarily unaccompanied by symptoms other than mild or moderate pallor. When it makes its appearance in the newborn period, however, icterus and increasing anemia may occur as early as the first or second day of life, and kernicterus may be a sequel. In later childhood the symptoms of a chronic hemolytic process may be more marked. Episodes (crises) of weakness, anorexia, dizziness, nausea, vomiting and abdominal pain, with or without icterus, may be the presenting symptoms in children who seem to be well between attacks, except for pallor. Mild degrees of icterus may occur in severe anemias of long duration, and the urine and feces may be highly colored. Manifestations of gallstone colic or obstruction of the biliary tract may be the first signs. The spleen is always enlarged, but only sufficiently to be palpable in about 60 per cent of patients. A slight fever may be present during crises. Cardiac murmurs of hemic origin are common with severe anemia, and there may be cardiac enlargement.

**Complications.** These are uncommon in children, but there may be chronic ulceration and pigmentation over the lower tibia or malleoli, membranous corneal opacities and optic atrophy. Pituitary dysfunction and hypogonadism have been attributed to hereditary spherocytosis. Motor development and intellectual capacity are not impaired, but linear skeletal growth and gain in weight may be retarded. The combination of hypoplasia at the base of the skull with widening of the marrow spaces of the flat bones of the skull may lead to parietal and frontal bossing and broadening of the face.

**Laboratory Data.** The erythrocyte count is reduced and may be as low as one million cells per cubic millimeter; the hemoglobin level is reduced in proportion. The anemia is normochromic and normocytic. The reticulocyte count is usually elevated and sometimes reaches levels as high as 20 to 30 per cent. A normal or low reticulocyte count may be

found for a day or two at times of aplastic crises. The leukocyte count may be strikingly elevated at times of active hemolysis, but during periods of chronic hemolytic activity both leukocyte and platelet counts may be below normal as a result of secondary hypersplenism. The peripheral blood smear shows anisocytosis. There are many large polychromatophilic erythrocytes, a sizable proportion of apparently normal cells, and variable numbers of small, deeply staining spherocytes. Similar spherocytes are usually seen in at least one parent of the child with hereditary spherocytosis.

The osmotic fragility of the erythrocytes is typically increased, but in 10 to 15 per cent of cases even carefully performed quantitative tests will fail to reveal abnormal fragility. Incubation of the erythrocytes in defibrinated whole blood under sterile precautions for twenty-four hours at 37° C. prior to testing will accentuate the abnormality in osmotic fragility.

In a small proportion of cells, the reticulocytes and immature erythrocytes, there may be increased resistance to destruction in hypotonic saline solution.

The serum level of indirect bilirubin is usually moderately elevated in older children, but rarely in the first few years of life; the direct bilirubin may be elevated if cholelithiasis has resulted in biliary obstruction. There may occasionally be falsely positive reactions to serologic tests for syphilis, which revert to normal after splenectomy. The Coombs' test is negative.

The bone marrow reveals hyperplasia of the erythroid series. Rarely the marrow may be hypoplastic with depression of erythrocytes, myeloid elements and platelets.

Microscopic examination of the spleen after surgical removal shows intense congestion of the pulp. The sinusoids and pulp spaces are lined with prominent endothelial cells. Hemosiderosis may be present.

**Differential Diagnosis.** Neither spherocytosis nor increased osmotic fragility is confined to this disease. Spherocytosis may be found in hemolytic anemias of other causes, including those resulting from acute infection, from iso-immunization, especially to the A or B blood groups, from auto-immunization or from chemical agents. In the absence of the trait of spherocytosis in other members of the family the possibility of some anemia other than hereditary spherocytosis must be carefully explored.

**Course and Prognosis.** The course is ex-

tremely variable. Many patients live active lives of average duration without therapy. When symptoms occur in childhood, however, one can anticipate that without treatment the chronic hemolytic process will lead to limitation of activity, stunting of growth and possibly to biliary tract disease or other complications. The danger of sudden severe crisis has perhaps been overestimated. Death can occur from anemia and cardiac failure if treatment is too long delayed.

With splenectomy and correction of any abnormality of the biliary tract the child can expect to lead a normal life. His offspring should be examined for the hereditary trait, however, in early life; even in the newborn period, if jaundice should occur.

**Treatment.** Splenectomy completely alleviates the anemia and accompanying symptoms in hereditary spherocytosis. After splenectomy striking changes occur in all the cellular elements of the blood. The erythrocyte count increases promptly by one to one and a half million cells per cubic millimeter, and the leukocyte count rises quickly to levels of thirty to forty thousand cells per cubic millimeter. A gradual increase in the platelet count beginning soon after operation reaches its peak by the eighth to tenth day, when it may exceed one million platelets per cubic millimeter. At this level the patient may be particularly susceptible to thrombosis, which in intra-abdominal or intracranial vessels may be serious. Adequate anticoagulant therapy with heparin should be initiated if the daily postoperative platelet count exceeds one million per cubic millimeter and should be continued so long as the platelet count remains above that level.

#### CONGENITAL NONSPHEROCYTIC HEMOLYTIC ANEMIA

A number of patients with familial hemolytic anemia resembling hereditary spherocytosis clinically but without spherocytosis have been studied recently. A dominant mode of inheritance is suggested. The affected children have a severe acute hemolytic anemia soon after birth, which continues as a mild or severe hemolytic process, represented by several ill-defined clinical patterns. Instead of spherocytes in the peripheral blood, varying numbers of macrocytes and, in some instances, ovalocytes are found. The red blood cells have decreased osmotic fragility in saline solution, but increased hemolysis in the autohemolysis test of Selwyn and Dacie. As in hereditary spherocytosis, there appears

to be a disturbance of energy metabolism in the erythrocytes.

Splenectomy is of no value. Steroid therapy was thought to be helpful in one patient with a severe hemolytic process.

#### THALASSEMIA

(COOLEY'S ANEMIA, ERYTHROBLASTIC ANEMIA, MEDITERRANEAN ANEMIA)

Thalassemia is a chronic hemolytic anemia in which the defect leads to the production of cells of abnormal shape, which are deficient in hemoglobin and are destroyed at an excessive rate. The primary defect appears to be inability to produce cells capable of normal incorporation of hemoglobin rather than inability to produce hemoglobin. The delivery of erythrocytes to the peripheral blood is decreased in severely involved patients to as little as 15 per cent of normal.

Thalassemia occurs in two forms. If the gene responsible for the defect is heterozygous, there is a mild anemia with moderate hypochromia, anisocytosis, poikilocytosis, and at times a slight splenomegaly. Carriers of a single gene for thalassemia are free of symptoms and live normal lives. Their asymptomatic condition is called *thalassemia minor*.

The child of two parents with thalassemia minor may be *homozygous* and have a severe, progressive anemia, *thalassemia major*, which is incompatible with long life and is only temporarily responsive to supportive transfusion therapy.

In each form hematopoietic tissue effects a partial compensation by persistent production of fetal hemoglobin at levels above normal values. In thalassemia minor this compensatory activity is relatively inconspicuous; though it is greater in thalassemia major, it falls far short of the need for effective oxygen transport.

Thalassemia, first described by Cooley in Detroit, was for some time found almost exclusively in persons whose familial origins were in certain countries bordering the northern Mediterranean coast, particularly Italy, Greece and Sicily. It has now been described in people of oriental, Jewish, Negro and western European origins.

**Clinical Manifestations.** In thalassemia minor the clinical manifestations are limited to moderate pallor and, on occasion, slight enlargement of the spleen. The condition is usually not recognized unless careful blood studies are obtained as part of a family survey.

Thalassemia major is characterized by the

onset of a severe and progressive anemia early in infancy. Anemia is not present at birth, but seems to develop in relation to the normal gradual decrease in production of fetal hemoglobin. Pallor is usually marked, and there is often mild icterus. Splenomegaly appears early, is progressive and may attain enormous proportions within a few years. In the absence of supportive transfusion therapy the anemia of thalassemia is relentlessly progressive and leads to cardiorespiratory distress and cardiac failure. Hemic murmurs and cardiac enlargement are common.

After months or years of transfusion therapy the clinical features of hemosiderosis usually become manifest. The possibility of a fundamental defect in control of iron absorption has been postulated, since the amount of iron stored in the tissues is far in excess of that accounted for by the blood transfused. The distribution of the iron in tissues resembles more closely that seen in hemochromatosis than in hemosiderosis due to other hemolytic disease or to multiple transfusions. The skin becomes a muddy, bronze color, with which the pallid mucous membranes are in striking contrast. The liver may become enlarged, owing to the changes of hemosiderosis, and together with the splenomegaly (largely due to other aspects of the disease) may produce abdominal enlargement of such an extent as to be disabling at times. A mild degree of lymphadenopathy is common.

With the progression of thalassemia major the skeletal changes associated with chronic hemolytic anemia become strikingly evident and exceed the changes found in other hemolytic anemias. Thickening of the membranous bones of the face and skull leads to a mongoloid facies, with a tendency to protrusion of teeth. The hands become broad and heavy in appearance, owing to alterations in the metacarpal bones. Periodic transfusions of blood may minimize the degree of hyperplasia in bone marrow and consequently lessen the extent of skeletal deformities.

The roentgenographic abnormalities in thalassemia major have been described in detail by Caffey. The first changes occur by the end of the first year of life and consist in widening of the medullary spaces, thinning of the cortices and decrease in size of the bony trabeculae. The small bones of the hand may be the first site of detectable changes in tubular bones. There the cortices may be thinned, and the medullary cavities broadened, so that the bones seem to assume a rectangular rather than a tubular shape. In

older children the changes in the bones of the extremities regress, whereas the changes in the vertebrae, skull and pelvic bones persist and increase in intensity. The membranous bones of the calvarium show striking widening of the diploic spaces, with radiating bony trabeculae traversing the widened space to give a "hair-on-end" appearance to roentgenograms of the skull. Pneumatization of the paranasal sinuses and mastoid regions is retarded and may be absent until late in childhood. Overgrowth of the maxilla is a common finding and may result in serious malocclusion and in a toothy facial appearance.

**Laboratory Data.** The characteristic features of the peripheral blood in thalassemia become apparent within the first few months and persist throughout life. In both the major and minor forms there is a microcytic, hypochromic anemia.

In thalassemia minor the anemia is of only moderate degree. The hemoglobin level is likely to be 9 to 13 gm. per 100 ml. There is a compensatory polycythemia with erythrocyte counts of six to seven million cells per cubic millimeter. Mild or moderate anisocytosis is present, and some polychromatophilia is seen. Reticulocyte counts of 3 to 6 per cent are usual. The leukocyte and platelet counts are not affected.

In thalassemia major there is a severe anemia with profound hypochromia. The erythrocyte count is below the normal range, and the hemoglobin is reduced to an even greater extent. The erythrocytes show anisocytosis and poikilocytosis. There are many microcytes, with a minority of contrasting, large hypochromic cells 12 to 15 microns in diameter. The hemoglobin in these large cells is irregularly distributed, creating many bizarre shapes. The presence of a small central mass of hemoglobin may give them a "target-cell" appearance.

Rapid turnover of erythrocytes is reflected in the moderately elevated reticulocyte count and the presence of nucleated erythrocyte precursors. Stippled cells occur, and Howell-Jolly bodies and polychromatophilic cells may be numerous. The red blood cells in both thalassemia major and minor show a distinctly increased resistance to hemolysis in hypotonic saline solution.

A moderate leukocytosis is present in the early stages of thalassemia major; counts may be as high as twenty-five to thirty thousand per cubic millimeter. Later when secondary hypersplenism dominates the picture, a leu-

FIG. 304. Roentgenograms of skull and long bones of child with thalassemia. A, Skull: Note rarefaction of bones and spicule formation, creating appearance of "hair standing on end." B, Hand: Rarefaction of bones resulting from expanding marrow cavity is visible earliest in small bones of hands and feet. C, Lower extremity: Extreme rarefaction in a long-standing anemia of severe degree; the excessively wide marrow cavities and the thin cortical bones predispose to pathologic fractures.

kopenia will be found. Granulocytes are the predominant cells. Platelets may be slightly increased in the early phase of the disease, but may be reduced in number when hypersplenism occurs.

The serum level of indirect bilirubin is elevated in thalassemia major to levels of 2 to 3 mg. per 100 ml., with higher levels when hemosiderosis appears. The serum level of iron is in the high range of normal, and the serum iron-binding capacity is less than usual. The free protoporphyrin of the erythrocytes and the serum level of copper are elevated. The erythrocytes contain increased amounts of fetal hemoglobin long after the production of this pigment has practically ceased in normal children.

The bone marrow in thalassemia major is hypercellular, erythrocyte precursors being predominant. In long-standing cases foam cells resembling those of Gaucher's disease may be found. Similar cells are also found in the spleen, where there are numerous foci of extramedullary erythropoiesis, enlargement of fibrous trabeculae and infarcts.

**Diagnosis.** Thalassemia minor must be differentiated from the *anemia of iron deficiency*. This may be difficult on casual examination. In thalassemia minor the erythrocyte count will be normal or elevated. The reticulocyte count will be slightly elevated in thalassemia minor, but usually not in iron deficiency states. Study of the parents of the child with thalassemia minor will always

show that one or both have blood findings compatible with that diagnosis.

Thalassemia major must be differentiated from other hemolytic anemias of early infancy which may be associated with splenomegaly. Usually the hypochromia and anisocytosis in peripheral blood will exclude other hemolytic conditions, as will the finding of decreased rather than normal or increased osmotic or mechanical fragility. Family studies will also aid in the establishment of the diagnosis of thalassemia major; *both* parents will have thalassemia minor.

The *sickle cell trait* may exist in patients with thalassemia minor (p. 952). Ordinarily the clinical pattern of this unusual combination more closely resembles that of sickle cell disease than of thalassemia major.

**Course and Prognosis.** Thalassemia minor is a benign condition and does not interfere with normal activity. Persons with this condition should be cautioned that if they marry another person with the same trait, their children may have the major form. On the average, one quarter of their children would be so affected.

Children with thalassemia major are dependent from early infancy upon transfusion therapy, the frequency of the need often increasing as they become older. Even with the best of care they are usually severely limited in activity and often stunted in growth. Many acquire hemosiderosis, and hemochromatosis may be a terminal complication. Cardiac failure is a constant threat, and only a few patients have survived the childhood years; a few with relatively mild involvement have lived into late adulthood. There may be some lessening of severity after puberty.

**Treatment.** Thalassemia minor requires no treatment. The anemia of thalassemia major is controlled only by transfusion of blood, which should be given as often as necessary to maintain the hemoglobin level above 6 gm. per 100 ml. (40 per cent of normal). More vigorous therapy appears to add little to the comfort or well-being of these children. The use of sedimented cells will increase the efficiency of a given amount of transfusion. Such transfusions, if given slowly and carefully, may also lessen the danger of cardiac embarrassment during the procedure. Although febrile and allergic reactions to plasma occur with some frequency, the washing of transfused cells with saline solution is rarely, if ever, indicated. The prophylactic use of aspirin with antihistaminic drugs may be effective, and in reac-

tions of unusual severity cortisone has been beneficial.

The results of splenectomy are difficult to evaluate. When there is massive enlargement, relief from the mechanical load justifies the operation. Splenectomy has appeared on occasion to prolong the interval between needed transfusions and to result in more nearly normal growth and activity. When leukopenia and thrombocytopenia of moderate or severe degree indicate secondary hypersplenism, some benefit from splenectomy might be expected.

The administration of iron, liver extract or cobalt has no place in the treatment of thalassemia, and oral therapy with iron may dangerously accentuate the hemosiderosis.

It is important that the families of these children be helped to accept the unfortunate situation and to provide the opportunity for them to lead as nearly normal lives as possible. With adequate management and understanding children with thalassemia major are often able to lead satisfactory lives.

## SICKLE CELL DISEASE

### (DREPANOCYTOSIS, MENISCOCYTOSIS)

Sickle cell disease is characterized by a persistent hemolytic anemia with intermittent episodes of painful crises, during which the hemolytic process may be accentuated. The disease is associated with an inherited defect in the synthesis of hemoglobin and occurs almost exclusively in the Negro race. When the defect in synthesis of hemoglobin is inherited in the heterozygous state, an asymptomatic condition (*sickle cell trait*) can be identified; it is found in 7 to 13 per cent of Negroes in the United States. When the inherited abnormality appears in homozygous form, sickle cell disease results.

In both the heterozygous and homozygous forms the presence of an abnormal hemoglobin (hemoglobin S) can be identified by electrophoretic means. This type of hemoglobin has the distinctive property of forming long crystalline structures (tactoids) under reduced oxygen tension. This property is thought to be responsible for the sickled shape of the erythrocytes of both heterozygous and homozygous carriers.

Both parents of the person with the homozygous trait (sickle cell disease) are heterozygous (sickling trait). On the average, three quarters of the children of such parents have the sickling abnormality, and one quarter have sickle cell disease. It has been un-

usual for a parent to have the active form of the disease.

**Pathogenesis and Pathology.** The alterations in sickle cell disease are related to chronic hemolytic anemia and to interference with the blood supply of various tissues. The vascular lesions result from capillary obstruction, which may depend upon the abnormal shape of the erythrocytes. It is believed that at times of crises the number of sickled cells may be increased and that sequestration of them in local areas leads to anoxic changes which promote further sickling and further obstruction. Infarcts may thus occur in many organs, most commonly the spleen, and less often in bone, the gastrointestinal tract, kidneys, lungs, heart and brain. Thrombosis is an occasional complication.

At intercritical times the spleen (and to a less extent other areas) is the site of continuous removal of abnormally shaped cells. Infarctions of the spleen are common, and after the age of five to seven years may lead to striking fibrosis and atrophy. The trabeculae become greatly thickened, and calcium and iron are deposited. Atrophy may be so extreme that the organ effectively disappears after the age of twelve. Hemosiderosis occurs in the liver, largely the result of repeated blood transfusions. As in other chronic hemolytic anemias, cholelithiasis is common in patients living to adulthood.

**Clinical Manifestations.** The sickle cell trait is not accompanied by clinical symptoms unless it is associated with some other defect in the synthesis of hemoglobin (see p. 952), or with exceptional circumstances, such as flight in aircraft at high altitudes, when hypoxia may provoke splenic infarction.

Clinical manifestations of sickle cell disease do not appear until the second or third month of life, when the normal fetal hemoglobin is largely replaced by the abnormal hemoglobin S. In mildly affected children, sickle cell disease may not be evident until late in childhood; 30 to 50 per cent of all affected ones manifest symptoms by one year of age.

The initial manifestation is often the so-called crisis, an acute disturbance accompanied by a variety of manifestations, the most common of which are severe abdominal pain and pain in the legs. The abdominal pain is commonly associated with absence of bowel sounds and with boardlike rigidity of the abdominal wall, and it is often impossible to differentiate conditions requiring surgical intervention. Pain in the extremities may be

muscular, or osseous, or may be localized to joints, which may be hot and swollen. Other less common manifestations are severe flank pain sometimes with hematuria, priapism presumed to be due to thrombosis of small vessels in the penis, convulsions, syncope, stiff neck, coma or localized paralyses. The chronic pallor may be greatly accentuated at the time of crisis. About forty-eight to seventy-two hours after onset of a crisis icterus will usually appear and may become marked.

Except in crisis, the manifestations are those of a chronic hemolytic process, viz., anemia and pallor. Icterus may be persistent in late childhood and in severely affected persons. Older children are likely to have long thin extremities, a short trunk, protruding abdomen and barrel chest, but they usually attain average heights and weights.

Under the age of nine years the spleen will often be palpable; later it is less likely to be felt. Enlargement of the liver is not common. Cardiac enlargement and apical blowing systolic murmurs are common; the latter may be transmitted to the left axilla and be indistinguishable from murmurs of rheumatic heart disease. Ulcerations over the lower tibia and malleolar areas, common in adults with sickle cell disease, are rare in children.

**Laboratory Data.** The "sickled" shape assumed by the erythrocyte under conditions of low oxygen tension is characteristic. At times of crisis sickled forms may be abundantly demonstrated in ordinary smears of peripheral blood. When not so demonstrated, they may be produced in many ways. Commonly a small drop of blood is placed under a cover slip and sealed off from oxygen by petroleum jelly. After incubation for one to twenty-four hours at room temperature sickled forms will usually appear. Other methods include the incubation of erythrocytes with suspensions of aerobic bacteria, or the exposure of erythrocytes to any of several potent reducing agents, such as sodium meta-bisulfite. It is a good rule not to accept less than three negative tests as final evidence when sickle cell disease is suspected.

*Tests for sickling do not distinguish between the sickle cell trait and sickle cell disease.* In sickle cell disease the sedimentation rate of unoxygenated blood is low even in the presence of severe infection. An increase in the sedimentation rate of such blood to more than 20 mm. per hour (Westergren) after oxygenation is a strong indication of sickle cell disease. Occasionally only quantita-

tive electrophoretic determination of the amount of sickle cell hemoglobin can *absolutely* differentiate trait and disease. More than 60 per cent of the hemoglobin in red blood cells is abnormal in sickle cell disease, whereas less than 45 per cent is abnormal in sickle cell trait. Hemoglobin S can also be distinguished by its amino acid content. Fetal hemoglobin as well as hemoglobin S is produced in increased amounts in sickle cell disease.

The erythrocyte count and hemoglobin level are not abnormal in persons with simple sickle cell trait. In sickle cell disease the level of hemoglobin may be in the range of 6 to 9 gm. per 100 ml., except at times of crisis, when it will be lower. Each affected person tends to stabilize at a level at which he is able to balance hemolysis by his increased erythropoietic activity; any increase from transfusion of blood is temporary. Rarely a patient may be able to maintain a balance within the lower limit of the normal range.

There may be a moderate degree of hypochromia, the reason for which is not known, since iron deficiency is not ordinarily present. The reticulocyte count is moderately elevated to 5 to 25 per cent, with the highest values five to seven days after crises. On occasion reticulocytes may be absent early in the course of a crisis, and there may be hypoplasia of erythroid elements in the marrow in contrast to the usual hyperplasia. The osmotic fragility of the erythrocytes shows increased resistance in hypotonic saline solution.

The leukocyte count is moderately elevated and may reach thirty to fifty thousand cells per cubic millimeter at times of crisis. Immature myeloid cells are commonly present, and granulocytes predominate. Platelets are usually normal in number.

Although no defect of renal glomerular or tubular function is characteristically demonstrable, the urine usually has a low specific gravity. Proteinuria is not uncommon, and spontaneous, painless hematuria may occur with sickle cell trait as well as sickle cell disease.

The serum level of bilirubin, principally indirect pigment, is consistently moderately elevated. Four to seven days after the onset of crises the level will increase temporarily. There may be an increase in protein, leukocytes and erythrocytes in the cerebrospinal fluid, when sequestration of cells occurs in the central nervous system at times of crisis or in patients suffering from a cerebral thrombosis. Abnormalities in electroencephalo-

graphic tracings are often found during crises.

Roentgenograms of the skull, long bones, vertebrae, hands and feet may show widening of medullary spaces and thinning of cortices. Infarction of large areas of bone often leads to extensive changes similar to those of osteomyelitis.

**Differential Diagnosis.** There is hardly a clinical pattern which might not be duplicated by sickle cell disease, since any organ system may be the site of vascular occlusion during crises. A test for sickling should be obtained on every Negro patient.

When sickling is demonstrated in the patient and in both parents, the presence of a hemolytic anemia will suggest sickle cell disease. If a hemolytic process of another origin, such as hereditary spherocytosis or acquired hemolytic anemia, were to occur in a patient with sickle cell trait, differentiation from sickle cell disease would rest upon clinical and laboratory features. The sickling trait may be associated with other abnormal hemoglobins or with the trait for thalassemia (p. 952). Occasionally only electrophoretic studies of the hemoglobin will disclose the true nature of the hemic disturbance.

The roentgenographic rarefaction and sclerosis of bone in sickle cell disease may suggest syphilis, tuberculosis, osteomyelitis, aseptic necrosis or a tumor.

Cardiac enlargement and murmurs, joint pains and epistaxis are suggestive of rheumatic fever in children in whom sickling can be demonstrated. Electrocardiographic changes may be similar in the two diseases, but the demonstration of a hemolytic anemia favors sickle cell disease.

**Course and Prognosis.** The crises of sickle cell disease tend to occur less frequently with increasing age; they are more common in the fall and spring months in temperate climates.

The prognosis of sickle cell disease must be guarded, since fatal cerebral, cardiac or hemolytic difficulties may occur with little notice. Cholelithiasis may occur in the older child. Adults with sickle cell disease are said to have hypogonadism and relatively low fertility. The life expectancy of an infant or young child with sickle cell disease is less than average, but with careful supervision many may reach adult life.

**Treatment.** Treatment consists in supportive measures such as blood transfusions, protection against infection and help in social and vocational adjustment.

The treatment of crises involves relief of

pain, maintenance of hydration and, on rare occasions, the transfusion of erythrocytes. Codeine and aspirin may be only partially effective in the control of pain. During the first twenty-four to forty-eight hours of a critical episode vigorous oral hydration with water free of electrolytes may help to reverse sickling and thus help to relieve local vascular obstructions. Prompt and adequate antibiotic therapy should be given for any coexisting bacterial infection.

The advisability of blood transfusion must be evaluated according to individual needs. At times of crisis, when the level of hemoglobin may fall rapidly to 4 gm. per 100 ml. or less, if symptoms of hypoxia are absent, it is often possible through supportive measures, particularly oxygen and hydration, to avoid transfusion. In such cases the hemoglobin level will rise promptly and spontaneously after the crisis to its previous level. Transfusion therapy is indicated much less frequently than is generally considered to be the case.

Iron, liver extract and vitamins have no effect on sickle cell disease. Splenectomy apparently has no effect; secondary hypersplenism is rarely a problem.

#### SICKLE CELL—THALASSEMIA DISEASE (MICRODREPANOCYTOSIS)

An anemia associated with inheritance of genes both for production of sickle cell hemoglobin (hemoglobin S) and for thalassemia minor has been identified. It has been found most often in persons of Italian and Sicilian origin. Most persons affected have a mild, apparently modified form of sickle cell disease, with the onset in late rather than early childhood; on occasion the disturbance may more closely resemble thalassemia. The diagnosis of *combined sickle cell trait and thalassemia minor* is suggested when a chronic hemolytic anemia is found in a person of Mediterranean ancestry whose erythrocytes sickle and show marked hypochromia and when only one of the parents has the sickling trait. The other parent will usually have thalassemia minor. It is possible, however, for a person with the genes for both thalassemia and sickling to transmit *both* to a child.

#### OTHER HEMOLYTIC ANEMIAS ASSOCIATED WITH ABNORMAL HEMOGLOBINS

The identification of many hemoglobins of unusual molecular structure followed the identification of the molecular abnormality in hemoglobin S of sickle cell disease. To date

more than ten distinct varieties of abnormal hemoglobins have been identified in patients with hemolytic disease; probably many more remain to be identified. It has become customary to designate the various hemoglobins by letters as they are reported: hemoglobin A is adult hemoglobin; hemoglobin F, the fetal variety; hemoglobin S, sickle cell hemoglobin; and C, D, E, G, H; I, J, K, and so on, designate other varieties of abnormal hemoglobins.

In a patient with an otherwise unexplained chronic hemolytic process consideration must be given to the possible existence of an abnormal hemoglobin; no geographic or racial group appears to be free of these genetic abnormalities. The abnormality may exist in an asymptomatic, heterozygous state analogous to the sickle cell trait, in a homozygous symptomatic state, or most commonly as a double heterozygote; in the last instance hemolytic disease results from destruction of erythrocytes which contain two abnormal hemoglobins. Hemoglobin S has been commonly found with hemoglobin C, as well as with D and G; other hemoglobins have been described with the trait for thalassemia.

The abnormal hemoglobins are most often recognized through their characteristic electrophoretic patterns; differences in solubility, spectrophotometric patterns and amino acid content can be demonstrated for many and may be essential to the identification of certain ones. Fetal hemoglobin is differentiated from the others by its ability to resist denaturation in alkaline solution.

In persons with these abnormalities of hemoglobin, treatment is limited to blood transfusions when anemia is severe. In most instances hemolysis is only moderately severe and is generally compensated by hyperactivity of the bone marrow.

#### ELLIPTOCYTOSIS

Small numbers of elliptical-shaped erythrocytes may be encountered in peripheral blood films in a wide variety of anemias. A genetically controlled abnormality in which 50 to 90 per cent of the erythrocytes are oval or elliptical occurs in about 0.04 per cent of the population. About one in eight of such persons has a hemolytic process. The abnormality in erythrocyte structure is inherited as a mendelian dominant trait.

Elliptocytes are not found in conspicuous numbers at the time of birth in these patients, but appear in increasing numbers up to the age of three to four months, when the num-

ber becomes constant. The affected person may have no evidence of hemolytic anemia, or may have a mild, well compensated hemolytic process without symptoms, or may have a chronic hemolytic anemia. In the last instance splenectomy is often of symptomatic benefit.

#### ACQUIRED HEMOLYTIC ANEMIAS

The acquired hemolytic anemias of childhood are a heterogeneous group of disorders; among possible causative factors are (1) toxic substances with hemolytic properties, (2) idiosyncratic susceptibility to hemolytic effects of certain drugs or vegetable substances, (3) infections in which the erythrocyte is directly involved, (4) specific antibodies against red blood cells. The last group includes (a) acquired hemolytic anemias associated with autoagglutinins, (b) blood transfusion reactions and (c) iso-immunization (erythroblastosis fetalis). Because these three conditions present unique features, they are discussed separately.

The other acquired hemolytic anemias of childhood have many features in common, as well as distinctive aspects.

The clinical onset is typically abrupt. Nausea and vomiting or fever and abdominal pain may be the first signs, or hemoglobinuria may be the initial evidence. The child becomes irritable, lethargic, pale and often icteric. The liver may become enlarged; the spleen is regularly so after a day or two and may be tender. Hemic murmurs, tachycardia and cardiac failure may accompany severe anemia. If recovery occurs, relapses or recurrences are rare. Chronic forms may be seen, especially when immune bodies occur.

*Examination of the blood* usually shows a normocytic and normochromic anemia, which may be mild or profound. Regenerative activity is manifest by polychromatophilia and reticulocytosis (up to 60 per cent or more) and by a considerable degree of macrocytosis. Nucleated erythrocytes are occasionally found in the peripheral blood, and spherocytes, fragmentation of erythrocytes and Heinz bodies are often present. Erythrophagocytosis is common in peripheral blood and in marrow. When there is spherocytosis, the osmotic and mechanical fragilities may be increased. A granulocytic leukocytosis is common during or after acute hemolytic episodes and may reach levels of 50,000 cells or more per cubic millimeter. Platelet levels may be above normal.

Hemoglobinemia may be demonstrated, and hemoglobinuria may give the urine a bright red or port-wine color. Mild hematuria may also occur. Serum bilirubin may be moderately elevated with respect to indirect-reacting pigment. Large amounts of urobilinogen can be demonstrated in urine and may give the feces an orange tint.

**Specific Features of Certain Acquired Hemolytic Anemias.** Acquired hemolytic anemias of *toxic* origin owe their occurrence (1) to the direct lytic action of drugs, chemicals or bacterial products upon the erythrocyte, or (2) to a defect in the patient which makes his erythrocytes susceptible to hemolysis upon exposure to an otherwise nonhemolytic substance.

In the first category of toxic hemolytic processes are those associated with exposure to lead, potassium dichlorate, benzol and related compounds, the nitro derivatives of toluol and phenol, certain snake venoms and the toxic products of certain bacteria, notably the colon bacillus and hemolytic *Streptococcus* (in infancy) and *Clostridium welchii*.

In the second category hemolytic anemias have been observed in "sensitive" but otherwise normal persons after exposure to a variety of substances, including the sulfonamides, primaquine, naphthalene metabolites, nitrofurazone, vitamin K analogues, fava beans (p. 1388) and probably many other agents. A common enzyme defect, which is genetically controlled and is concerned with glutathione metabolism of the erythrocyte, is responsible for the development of the hemolytic state (p. 264). Red blood cells of affected persons have a low concentration of reduced glutathione as a result of a deficiency of the enzyme glucose-6-phosphate dehydrogenase. The enzyme defect can be demonstrated by measuring the concentration of reduced glutathione or by performing the "glutathione stability test."

Exposure to naphthalene is a relatively common cause of hemolysis in affected children, occurring most often from the ingestion of moth balls. In favism the onset occurs in the susceptible person a few hours to a day or two after ingestion of the broad bean (*Vici fava*) or inhalation of its pollen or dust. The hemolysis in any of these chemically induced anemias can be severe; resulting in prostration, extremely low levels of hemoglobin, icterus and hemoglobinuria. Transfusion of erythrocytes is necessary in severe cases, but in most instances the anemia is self-corrective. Removal of the toxic substance from the environment is essential to

prevent further hemolysis. Determination of the glutathione levels in the red blood cells of other members of the patient's family should be obtained when possible to identify apparently healthy persons who might experience hemolysis from exposure to offending chemical agents.

Severe *burns* are commonly accompanied by hemolysis and hemoglobinuria, which seem to depend upon thermal injury to red blood cells and upon toxic factors.

Direct *parasitization of the erythrocyte* occurs in malaria and in Oroya fever (*Bartonella bacilliformis*). Malaria is probably responsible for more hemolytic anemia than any other single condition (p. 606).

#### ACUTE HEMOLYTIC ANEMIAS ASSOCIATED WITH AUTO-AGGLUTININS

Acquired hemolytic anemia associated with the development of *auto-agglutinins* may occur under a variety of conditions, as, for example, with leukemia or other malignant processes, with infectious mononucleosis, atypical pneumonias and other infections, and at times without apparent association with another process (Lederer's anemia). The condition may be considered the prototype of several blood diseases (idiopathic thrombocytopenic purpura, anaphylactoid purpura, lupus erythematosus) in which the affected person forms antibodies against his own tissues. A hemolytic anemia may accompany *paroxysmal cold hemoglobinuria*, which is encountered in some children with congenital syphilis (p. 1022).
